rather than the order in which they are observed, this tree is often the most amenable to augmentation of hypotheses. In particular, unlike with many other trees, most of the probabilities associated with other possibilities can remain unaltered. For example, if we decide to consider a new possibility that the suspect dry cleaned her skirt so that any fibers would be found only with a small probability, then the path below could be changed to: culprit sits on sofa, a detectable fiber is transferred to her skirt, the suspect *does not dry clean her skirt*, the police decide to analyze the skirt, the police detect the fiber on the skirt, the police take the suspect to court, the court finds the suspect guilty. The associated path also appears (having very small probability): culprit sits on sofa, a detectable fiber is transferred to her skirt, the suspect *dry cleans her skirt*, the police decide to analyze the skirt, the police detect the fiber on the skirt, the police take the suspect to court, the court finds the suspect guilty.

Relationships to Other Graphical Decision Problem Representations

One problem with trees of all kinds is that although they represent asymmetric problems very well, nowhere in their topology is an explicit representation of hypotheses about dependence relationships between the state and measurement variables in the system. Such qualitative information is often elicited. For example, in the case study above, we have elicited for the police the qualitative information that the discovery of a fiber on the skirt is independent of the discovery of a fiber on the blouse, given the suspect sat on the sofa. Such statements tell us that many probabilities labeling the edges of a normal form or causal tree are equal to each other. However, this important information is not represented in the topology of the tree. On the other hand, it can be very easily represented by a Bayes Net, influence diagram (see **Influence Diagrams**), or other topological structures (see e.g. [7–9] and references therein). Elsewhere, we discuss a decision analysis (see **Decision Analysis**) using influence diagrams (see **Influence Diagrams**). Unlike decision trees, these structures can code continuous problems as effectively as discrete ones. Influence diagrams are, nevertheless, no panacea. In particular, they are only powerful when the decision problem has

close to a symmetric structure (in a sense defined in **Influence Diagrams**). So recent developments, both descriptive and algorithmic, often toggle between the two representations, simultaneously exploiting their different expressiveness (see e.g. [10]).

Default Correlation

A firm or an obligor is said to default on its debt when it cannot adhere to the payment schedule or other restrictions specified in the contractual agreement with its lenders. Examples of this include missed payment of interest or principal, a filing for bankruptcy as well as a distressed exchange. Joint default risk, or correlation between defaults, refers to the correlation between default events or default (or survival) times. The term is also sometimes applied to the correlation between changes in the default probabilities of individual firms.

Although default risk for an individual firm has been studied for several decades, it is only recently that the academic and the investment communities have focused on attempts to understand and model joint default risk. This interest has been driven primarily by the development of the credit derivatives market with financial products like collateralized debt obligations (CDO) whose payoff explicitly depends (*see Nonlife Insurance Markets; Credit Value at Risk*) on correlated defaults. Issuance of cash CDO reached (*see Potency Estimation; Credit Risk Models; From Basel II to Solvency II – Risk Management in the Insurance Sector*) \$268 billion in 2005 and that of synthetic CDO exceeded \$300 billion (2006 Structured Credit Insight, Morgan Stanley).

There is ample empirical evidence that defaults across firms are not independent. Figure 1 from Das *et al.* [1] graphs the number of defaults in North American firms by month over the period 1979 to 2004. The periods of significant clustering of default events coincide, as might be expected, with times of economic and financial stress like the 1991–1992 and 2001 US recessions.

There are at least three hypotheses regarding why defaults may be correlated. First, defaults may be correlated because firms are exposed to common or correlated risk factors. For example, Figure 1 suggests a common dependency on the economy. Second, there may be “contagion” between firms that have a contractual or other relationships with each other so that the default of one of the firms impacts the probability of default of the other firms to which it is related. The collapse of Penn Central Railway in 1970 – at the time, the largest railroad in the United States – resulted in the default of other

regional railroads. Third, default of firms may be correlated because of “frailty”. That is, suppose that there is a common default covariate that impacts the default risk of firms but it cannot be observed (or is observed imperfectly). Then, the default of a firm reveals information of this missing covariate and thus causes the default probability of other firms to be updated. Thus, even though there are no contagion-type effects, the default event of a firm impacts the probability of default of another firm. An example of frailty is the possible presence of accounting irregularities as implicated in the bankruptcy of Enron, whose default brought upon increased scrutiny of other firms.

There have been two main approaches to modeling and calibrating joint default risk. The first approach starts by modeling the default risk of an individual firm and then introducing joint default risk, for example, by allowing for a correlated default covariate across firms. The two principal theoretical setups for modeling the default risk of an individual firm are the structural model of Merton [2] and extensions thereof, and the reduced form models of Madan and Unal [3], Duffie and Singleton [4], and others. The second approach assumes that default probabilities of individual firms are exogenously available, and thus directly models joint default risk by allowing for a copula correlation.

Correlated Default in Structural Models

In Merton [2], default is (*see Credit Value at Risk*) assumed to occur only at maturity if the firm value is less than the face value of debt. Let the time t firm value V_t follow a geometric Brownian motion,

$$dV_t = \mu V_t dt + \sigma V_t dW_t \quad (1)$$

where μ is the instantaneous expected rate of return for the firm, σ is the volatility or diffusion parameter, and W_t is standard Brownian motion. The firm’s capital structure consists of equity, S_t , and a zero-coupon bond, B_t with (*see Numerical Schemes for Stochastic Differential Equation Models; Simulation in Risk Management*) maturity $T \geq t$ and face value of F . Then, the firm defaults if $V_T < F$. Let the

Figure 1 Intensities and Defaults. Aggregate (across firms) of monthly default intensities and number of defaults by month, from 1979 to 2004. The vertical bars represent the number of defaults, and the line depicts the intensity. The figure is taken from Das *et al.* [1] and explanation for the computation of the aggregate default intensity is provided therein [Reproduced from [1] with permission from The American Finance Association, © 2007.]

probability of default be $P[V_T < F]$. We can explicitly derive the probability,

$$\begin{aligned} P[V_T < F] &= P\left[V_{it}e^{\left(\mu - \frac{1}{2}\sigma^2\right)T + \sigma\sqrt{T}z} < F\right] \\ &= P[z < -DT D] \\ &= \Phi(-DT D) \end{aligned} \quad (2)$$

where z is a standard normal variate, $\Phi[\cdot]$ is the cumulative normal distribution, and $DT D$ is the “distance-to-default” (see **Credit Risk Models; Default Risk**) defined as,

$$DT D = \frac{\ln\left(\frac{V}{F}\right) + \left(\mu - \frac{1}{2}\sigma^2\right)T}{\sigma\sqrt{T}} \quad (3)$$

Empirically, estimates of the $DT D$ have been shown to be predictive of defaults (see, for example, Duffie *et al.* [5]) and used in commercial applications by Moody’s KMV.

As the only stochastic variable in the Merton [2] model is the firm value, correlation between defaults between two firms occur through the correlation

between their respective firms’ values. Let each firm follow a diffusion process,

$$dV_{it} = \mu_i V_{it} dt + \sigma_i V_{it} dW_{it} \quad i = 1, 2 \quad (4)$$

where W_{1t} and W_{2t} are correlated with correlation coefficient ρ . Let P_1 and P_2 be their respective probabilities of default as defined in equation (2) and the joint probability of default as the probability that at maturity both $V_{1,T} < F_1$ and $V_{2,T} < F_2$,

$$\begin{aligned} P(V_{1,T} < F_1, V_{2,T} < F_2) &= \int_{-\infty}^{DT D_1} \int_{-\infty}^{DT D_2} \frac{1}{2\pi\sqrt{1-\rho^2}} \\ &\quad \times \exp\left[\frac{z_1^2 - 2\rho z_1 z_2 + z_2^2}{2(1-\rho^2)}\right] dz_1 dz_2 \end{aligned} \quad (5)$$

The correlation between defaults, ρ^D , can then be computed as,

$$\rho^D = \frac{P(V_{1,T} < F_1, V_{2,T} < F_2) - P_1 P_2}{\sqrt{P_1(1-P_1)P_2(1-P_2)}} \quad (6)$$

Equation (6) explicitly relates the default correlation to asset correlations. Estimates of asset correlations are provided in Akhavan *et al.* [6].

Figure 2 Debt and Volatility over 1987–2000. The plot from Das *et al.* [9] graphs the median debt fraction (D/V) and the firm return volatility (σ_V) of firms in each rating category for each of the 166 months over the period January 1987 to October 2000. The firm value and the firm return volatility are estimated on a monthly frequency using Merton [2]. The debt is measured as the sum of current debt plus half the long-term debt. Firms with Moody's rating single-A or higher are classified as high-grade, Ba and Baa are classified as medium-grade, and single-B and C as low grade [Reproduced from [9] with permission from Institutional Investor, Inc. Journals Group, © 2006.]

The Merton model can be extended to allow for default prior to maturity by considering default to have occurred the first time the firm value breaches a threshold [7]. Zhou [8] provides an explicit derivation of the joint default probability of two firms for such a model.

Although modeling the probability of joint default as a function of the correlation between the firms' asset value is intuitive, in practice, defaults may also be correlated as changes in firms' debt levels as well as in firms' volatilities are correlated. Figure 2 from Das *et al.* [9] plots, for each of three rating classes, the median debt level and firm volatility. It is clear that both debt levels and firm volatilities

vary over time and that these changes are correlated across firms in the economy. In particular, it appears especially important to account for the correlation of volatilities. Although it is possible to extend a Merton type model, given the difficulty of implementing and calibrating such extensions in a parsimonious framework, recent efforts have tended to focus on reduced form models.

Reduced Form Models

In reduced form models, given a properly defined probability space, default is an unpredictable event

occurring at the first jump time τ of a counting process governed by an intensity λ_t . That is, the conditional probability of default over a period between t and $t + dt$, conditional on surviving up to time t , is (in the limit) $\lambda_t dt$. If λ_t itself is stochastic, then τ is said to be doubly stochastic. The probability of survival of a firm up to time T is then equal to,

$$P(\tau > T) = E \left[\exp \left(\int_0^T \lambda_t dt \right) \right] \quad (7)$$

Explicit representations of equation (7) are possible for certain specifications for λ_t . In particular, when the stochastic differential equation for λ_t is an affine diffusion, then it is known from the results of Duffie *et al.* [10] that the solution of equation (7) is,

$$P(\tau > T) = \exp(a(t) + b(t)\lambda_t) \quad (8)$$

where $a(t)$ and $b(t)$ are solutions to a set of Riccati ordinary differential equations. Specific solutions for common specifications are available in Duffie *et al.* [10].

The doubly stochastic framework can be extended to n firms by allowing each firm to have its own intensity process, λ_{it} , $i = 1, \dots, n$. The first default time $\tau = \min(\tau_1, \dots, \tau_n)$ has the intensity $\Lambda_t = \sum_{i=1}^n \lambda_{it}$. Therefore, the conditional probability of survival of all firms up to time T is also given by equation (7) with Λ_t substituted for λ_t . That is, consider the joint survivorship event defined as $\{\tau_1 > t_1, \dots, \tau_n > t_n\}$ for any set of times $t_1 \leq t_2 \leq \dots \leq t_n$. For any time $t < t_1$,

$$P(\tau_1 > t_1, \dots, \tau_n > t_n) = E \left(\exp \left(- \int_t^{t_n} \Lambda_s ds \right) \right) \quad (9)$$

where Λ is the sum of the intensities of the n firms surviving at time t .

In the doubly stochastic framework, conditional on the information at time t , each default event is independent. The only source of correlation between default times is from the correlation between the intensities, λ_{it} . This provides a natural setting for testing the hypothesis of whether common or correlated factors affecting the default intensities are sufficient to explain the distribution of defaults. Das *et al.* [1] provide the theoretical framework for such a test.

Proposition Das *et al.* [1] Suppose that $(\tau_1, \dots, \tau_n)$ is doubly stochastic with intensity $(\lambda_1, \dots, \lambda_n)$. Let $K(t) = \#\{i : \tau_i \leq t\}$ be the cumulative number of defaults by t , and let $\Lambda_t = \int_0^t \sum_{i=1}^n \lambda_{iu} 1_{\{\tau_i > u\}} du$ be the cumulative aggregate intensity of surviving firms to time t . Then $J = \{J(s) = K(\Lambda^{-1}(s)) : s \geq 0\}$ is a Poisson process with rate parameter 1.

The empirical tests are based on the following corollary to the proposition.

Corollary Under the conditions of the proposition, for any $c > 0$, the successive numbers of defaults per bin,

$$J(c), J(2c) - J(c), J(3c) - J(2c), \dots$$

are iid Poisson distributed with parameter c .

That is, given a cumulative aggregate intensity (as, for example, plotted in Figure 1), the sample period can be divided into nonoverlapping time bins such that each bin contains an equal cumulative aggregate intensity of c . The doubly stochastic assumption then implies that the numbers of defaults in the successive bins are independent Poisson random variables with parameter c . Das *et al.* [1] test this implication using standard tests of the Poisson distribution.

Figure 3 plots the distribution for bin size 8 along with the corresponding theoretical Poisson distribution. It is apparent that the empirical distribution does not look like the theoretical distribution. In particular, the right tail is too “fat” compared with the Poisson distribution. The doubly stochastic property is rejected, suggesting that contagion- or frailty-type effects may also be important for understanding the clustering of defaults in the economy.

Modeling Correlated Default Using Copula

Let the marginal distribution providing the survival time (see **Comonotonicity; Simulation in Risk Management; Extreme Value Theory in Finance; Copulas and Other Measures of Dependency**) or default probability of each firm be given. The marginal distribution can be linked using a “copula” function, C , to create a joint distribution. The copula is a multivariate distribution function such that every marginal distribution is uniform on $[0, 1]$, and allows the separation of the marginal distribution from the

Figure 3 *Default distributions.* Das *et al.* [1]. The empirical and theoretical distributions of defaults for bin size 8. The theoretical distribution is Poisson [Reproduced from [1] with permission from The American Finance Association, © 2007.]

dependencies. Sklar [11] establishes that any multivariate distribution can be written in the form of a unique copula C if each of the univariate distributions are continuous.

A wide range of copula distributions have been proposed. The most commonly used copula as introduced by Li [12] is the Gaussian copula where,

$$C(z_1, \dots, z_n) = \Phi_n(\Phi^{-1}(z_1), \Phi^{-1}(z_2), \dots, \Phi^{-1}(z_n); \Sigma) \quad (10)$$

where $\Phi_n()$ is the multivariate normal distribution. The marginal distributions of z_i , $i = 1, \dots, n$ are Gaussian, and the copula links them together with the correlation matrix Σ . Another multivariate distribution that could be used as an alternative to the Gaussian is the t copula. There are also copulas that do not derive from multivariate distributions. These include a set of copulas called Archimedean copulas. Examples of the Archimedean copulas include the Gumbel and the Clayton copulas. The Gaussian copula is the most commonly used implementation in industry.

Li [12] provides illustrations of how the copula may be used to price a security that depends on joint default risk. Consider a first-to-default swap written on a portfolio of N names. For each firm i , let the distribution function for the survival time T_i be $F_i(t)$.

Assuming a Gaussian copula, the joint distribution of the survival times is,

$$F(t_1, \dots, t_N) = \Phi_N(\Phi^{-1}(F_1(t_1)), \Phi^{-1}(F_2(t_2)), \dots, \Phi^{-1}(F_N(t_N)); \Sigma) \quad (11)$$

Now to simulate defaults using the copula:

- Simulate N random numbers $z_1, z_2, \dots, z_N$ from an N -dimensional normal distribution with covariance matrix Σ .
- Obtain $T_1, T_2, \dots, T_N$ as $T_i = F_i^{-1}(\Phi(z_i))$, $i = 1, \dots, N$.

Given the default times from each simulation, the first-to-default time is the minimum of the default times of the N firms.

The copula methodology has been widely adapted in the industry as it does not require the development of a default risk model for an individual firm nor does it require a detailed modeling of the dependencies beyond the specification of the copula. That is, the dependency of defaults or survival times can be because of any common or correlated factors, contagion, or frailty. The use of copula may be considered a quick fix when sufficient empirical data is not available, or the underlying “true” economic model is unknown. This in turn is also the weakness of these models. They are difficult to calibrate to data and may not provide any additional economic insight.

Extensions

Given the empirical evidence that common and correlated factors may not be sufficient to model joint default risk and the limitation of copula-based models, there has been some recent effort in accounting explicitly for contagion (*see Credit Risk Models; Role of Alternative Assets in Portfolio Construction*) and frailty. As of yet, this effort should be considered in its infancy, especially for modeling contagion for which empirical evidence (apart from the well-known case of Penn Central) is scarce but see Davis and Lo [13]. There has been relatively more progress in the development of frailty models (for example, Giesecke [14] and Collin-Dufresne *et al.* [15]).

In particular, Duffie *et al.* [16] extend the model of Duffie *et al.* [5] by incorporating a frailty variable as an additional unobservable common default covariate. Empirically, the model improves upon the model without frailty by more closely explaining the right tail of defaults in the economy. For example, the actual number of defaults in the five-year period from January 1998 and December 2002 is 195. The model without frailty assigns almost zero probability to defaults being greater than 175. In contrast, for the model incorporating frailty, the realized number of defaults falls close to the 96th percentile. Thus, it appears that a model that allows for an unobservable variable may be of some use, especially when the right tail of defaults needs to be modeled.

Conclusion

In summary, there has been considerable progress in the modeling and the understanding of joint default risk. Earlier, efforts were made to extend structural models by allowing the stochastic variables to be correlated but these have been proved to be difficult to calibrate and implement in practice. More recent efforts have been toward extending reduced form models, where typically the correlation between survival times is driven only by the correlation between default intensities. Such a model does reasonably well, but underestimates the defaults in the right tail of the empirical distribution suggesting a role for frailty or contagion. There is ongoing effort especially in extending the existing models for frailty.

The rapid growth of the credit derivatives markets has required models that can be implemented for pricing securities. The industry has standardized in the use of the Gaussian copula for pricing products sensitive to joint default risk like CDOs. However, empirical evidence indicates that such a model fits only imperfectly (for example, the model fitted over different tranches of a CDO results in different correlations). It appears likely that the Gaussian copula will play a role similar to that of the Black–Scholes implied volatility in the equity markets in that it provides a convenient and easily implementable standard for comparative pricing.

In summary, there is much ongoing effort in both academic and the industry to understand and model joint default risk, and it is likely to remain for some time an area of rapid development.

Default Risk

In modern finance, default risk (*see Credit Risk Models; Options and Guarantees in Life Insurance; Informational Value of Corporate Issuer Credit Ratings*) is typically interpreted as the probability of default, and default occurs when a debtor firm misses a contractually obligatory payment such as a coupon payment or repayment of principal. The occurrence of default is always costly for the lender and often triggers bankruptcy proceedings, in which case the assets of the firm are liquidated and the proceeds of the sale used to pay creditors according to prespecified rules. Defaults are more prone to occur where the general economic environment is poor; losses in such circumstances are then particularly painful.

Assessing default risk helps potential lenders determine whether they should give loans in the first place; if they do so, it also helps them to decide how much to charge for default risk, what covenant conditions, if any, to impose on the loan agreement, and how to manage the default risk through the course of the loan period. The assessment of default risks is also critical in the valuation of corporate bonds and credit derivatives such as basket-default swaps.

There is an important distinction between default risk under the actual (or P) probability measure and that under the risk-neutral (or Q) probability measure (*see Equity-Linked Life Insurance; Premium Calculation and Insurance Pricing; Mathematical Models of Credit Risk*). In the former, default risk is assessed in terms of the probabilities of actual default occurrences. In the latter, default risk is assessed in terms of risk-neutral probabilities. Typically, a decision to lend would be assessed using the P measure, but decisions relating to pricing would be assessed under the Q measure. The Q measure would also be used when backing out estimates of default risk from the prices of traded securities.

When default occurs, the actual loss inflicted depends on the loss given default (LGD) rate. The LGD is a proportion between 0 and 1 and is typically expressed as $1 - R$, where R is the nonnegative recovery rate (*see Compensation for Loss of Life and Limb; Credit Scoring via Altman Z-Score; Credit Value at Risk*), the proportion of the loan subsequently recovered after default has

taken place. The expected loss per dollar exposure is therefore

$$PD \times LGD \quad (1)$$

where PD is the default probability under the P measure. Note that the expected loss is sensitive to what we assumed about the recovery rate R . The size of the loss also depends on the creditor's exposure at default (EAD), typically represented by the notional size of the loan. Thus, the expected loss is equal to

$$EAD \times PD \times LGD \quad (2)$$

Defaults are often modeled as Poisson processes. However, when dealing with losses on portfolios of default-risky instruments, it is important to take account of correlations between defaults; this gives rise to the notion of the concentration risk in a portfolio. Since the default process is a binary one (i.e., a particular loan either defaults or it does not), it follows that the distribution of losses on a loan portfolio (typically) has a small left hand tail starting from zero, a relatively small positive mean, and a long heavy right hand tail.

Credit Ratings

One of the oldest means of assessing default risk is through credit ratings. A credit rating is an expert assessment of the likelihood that a debt will be paid in full and on time. These ratings are traditionally produced by independent rating agencies (*see Enterprise Risk Management (ERM); Informational Value of Corporate Issuer Credit Ratings*) such as Moody's or Standard & Poor's (S&P) and are usually provided for the major debt issues of large corporates or sovereigns. So, for example, in the S&P system there are 10 ratings (AAA, AA, A, BBB, BB, B, CCC, CC, C, and D), with AAA being the highest rating and D indicating that default has actually occurred. The "A" and "BBB" ratings indicate high-quality issues and are often referred to as *investment grade*; the others indicate lower quality issues and are known as *junk bonds*; and "C" rated issues indicate that the issue is more or less vulnerable to default.

Ratings are based on factors such as the rating agency's assessments of the economic prospects of the issuing firm, the quality of its management, the risks implicit in its lines of business, and the

degree of security offered on the debt issue. Typically, the rating agency will go through publicly available information such as prospectus, annual reports, and regulatory filings and meet with the debt issuer to obtain further confidential information. It may or may not give the issuer the opportunity to respond to its preliminary findings. It will then usually publish the rating and any supplementary analysis on which it is based, and charge the issuer a fee for the rating. In other cases, the rating might be carried out completely independent of the firm being rated, and ratings might be revealed on a confidential basis to the agency's fee-paying clients.

Whether published or not, the rating has a critical bearing on a debt issue's reception in the marketplace: a poor rating will discourage many investors from taking it up, and those that do take it up will demand higher yields to compensate for the associated default risk. A poor rating on a bond will therefore lead to a lower bond price, and the desire to avoid such an outcome gives an issuer an incentive to cooperate with the rating agency and persuade them of its creditworthiness.

More recently, many financial institutions have developed their own internal risk rating systems, which they apply to their loans. These produce estimates of the probability of default on a particular loan, but many also produce estimates of the loss given default. Combined with information about exposure at default, this information enables a bank to estimate the expected loss on a loan. These models help banks manage their loan portfolios on a consistent and transparent basis, and are mainly used to rate credit risks and determine the capital charges to apply against them. For example, the capital charge might be equal to the expected loss multiplied by some adjustment factor that takes account of concentration risk and possible error in the model.

Contingent Claims Approaches

Some of the most important approaches to default risk are the contingent claim approaches (*see Actuary; Longevity Risk and Life Annuities; Credit Scoring via Altman Z-Score*) – sometimes also known as *structural approaches* – that originate from a seminal article by Merton [1]. The motivation for these approaches builds on the limited liability rule that allows shareholders to default on their obligations

provided they hand over all the firm's assets to creditors. The firm's liabilities are therefore contingent claims issued against the firm's assets, and under the basic model default occurs at maturity when the value of the firm's assets falls short of the value of its liabilities. Subject to certain simplifying assumptions, default risk can then be modeled using regular option pricing methods.

To illustrate this model in a simple form, consider a firm with assets V . These are financed by equity S and a single debt instrument with face value F maturing at time T . The market value of this instrument is B . Under standard assumptions, the value of the firm at time $t = 0$ is given by

$$V_0 = S_0 + B_0 \quad (3)$$

Default occurs at time T in the event such that $V_T < F$. Merton's insight was to regard the option to default as a put option on the firm's assets. If we make the additional assumptions needed to justify the Black–Scholes option pricing model (*see Risk-Neutral Pricing: Importance and Relevance; Statistical Arbitrage*) – a Gaussian diffusion process, and so on – then the value of this put, P_0 , can be shown to be

$$P_0 = -N(-d_1)V_0 + Fe^{-rT}N(-d_2) \quad (4)$$

where

$$d_1 = \frac{\ln(V_0/Fe^{-rT}) + \sigma^2T/2}{\sigma\sqrt{T}}, d_2 = d_1 - \sigma\sqrt{T} \quad (5)$$

and where $N(\cdot)$ is the cumulative standard normal distribution, r is the risk-free rate, and σ is the volatility rate of the firm's assets. We can now see that the cost of this option depends on the firm's leverage ratio Fe^{-rT}/V_0 (or the present value of its debt divided by the present value of its assets), σ , the term to maturity of the debt T , and r .

This option pricing approach allows us to recover other parameters of interest. For example, the probability of default under the Q measure is

$$\Pr[V_T < F] = N\left(\frac{\ln(F/V_0) - (r - \sigma^2/2)T}{\sigma\sqrt{T}}\right) \quad (6)$$

This tells us that the probability of default is increasing with F , decreasing with V_0 , and (for $V_0 > F$, as seems reasonable) increasing with σ , all of which accord with economic intuition.

An implication of a positive default probability is that the yield on the debt must exceed the risk-free rate to compensate the lenders for the default risk they are bearing. Under the Merton model (*see Credit Value at Risk*), the resulting default spread π – the difference between the yield on the debt and the risk-free rate – is given by

$$\pi = -\frac{1}{T} \ln \left(N(d_2) + \frac{V_0}{Fe^{-rT}} N(-d_1) \right) \quad (7)$$

which tells us that an increase in the leverage ratio leads to a rise in the spread. Since d_1 and d_2 themselves depend on σ , we can also infer that the spread rises with the volatility. Both of these results are again in line with economic intuition.

The Merton model can be extended in many ways. Extensions include first-passage time models, in which the firm is allowed to default not just at a fixed time T , but at some random time when the V hits a critical threshold; jump-diffusion models, in which the assumption of Gaussian diffusion is supplemented with a jump process in the value of the firm; and models with stochastic or endogenous default barriers. The univariate Merton model can also be generalized to multivariate cases: these allow us to determine the default risk associated with a portfolio of bonds or corporate debt.

A particularly influential version of the Merton model is the KMV model [2]. This model was developed in the 1990s by a private firm, KMV, named after its founders Kealhofer, McQuown and Vasicek. This model is widely used and [3] reports that 40 of the biggest 50 banks in the world use it. The model itself is a relatively straightforward extension of the Merton model, but its distinctive strength lies in its empirical implementation using a large proprietary database and in the quality of the empirical research underlying this implementation. Once the capital structure of the firm is specified, the KMV model allows one to estimate expected default frequencies (EDFs) for any chosen horizon period. The main modeling innovation in the KMV model is to introduce an additional state variable, the so-called distance to default, which is the number of standard deviations that a firm at any given time is away from default: the greater the distance to default, the lower the probability of default. The use of this variable allows for a more sophisticated relationship between default probability and asset value than is the case in the Merton model: it can accommodate the impact

of factors such as heavy-tailed asset values, more sophisticated capital structures, and the possibility that default will not automatically lead to liquidation. The actual inference from distance to default to default probability is obtained using KMV's proprietary software calibrated to their database of historical defaults.

The KMV model appears to perform well in practice. Evidence suggests that the EDFs of firms that subsequently default rise sharply a year or two before default, and that changes in EDFs also anticipate the credit downgrades of traditional rating agencies. Ratings agencies are often slow to adjust their ratings, and this can be a problem if the credit quality of a firm deteriorates suddenly, which often happens if a firm is close to default. The EDFs estimated by the KMV model will tend to react more quickly to such changes, because they are reflected in the share price and therefore in the firm's estimated distance to default. Another advantage of the KMV model is that its EDFs tend to reflect the current macroeconomic environment, which rating agencies tend to ignore. This means that KMV forecasts are more likely to be better predictors of short-term default probabilities than those based on credit ratings.

On the other hand, contingent claims approaches require information about firm values and volatilities that is often not available. Estimates of firm values have to be obtained from information contained in the firm's stock price and balance sheet, and such estimates are usually dependent on questionable assumptions about factors such as capital structure and the distribution of asset values. There are also downsides to the fact that KMV model takes account of stock price valuations: first, the KMV approach is difficult to implement for firms that are not publicly traded, precisely because it requires information on stock values; in addition, if the stock market is excessively volatile, the KMV model can produce estimates of default probabilities that are also excessively volatile. Estimates of volatilities are also difficult to obtain and are dependent on questionable assumptions about factors such as capital structure. For their part, multivariate versions of these models are also dependent on simplistic treatments of statistical codependence – most typically, that we can model codependencies between defaults using Pearson correlations, which implicitly assumes that the underlying risk factors are multivariate

elliptical – and these correlations are also difficult to estimate using the limited data available. A final weakness of many of these contingent claims models is that they ignore credit migration, i.e., they treat default probabilities as fixed over the horizon period, and this ignores the tendency of ratings to migrate over time.

Credit Migration Approaches

The next class of models are those built on a credit migration (*see* **Credit Migration Matrices**) or transition matrix that represents the set of probabilities that any given credit rating will change to any other over the horizon period. These probabilities can be inferred from historical default data, from the credit ratings themselves, or from models such as KMV. Typically, these probabilities will suggest that a firm with any given rating is most likely to retain that rating by the end of the horizon period; however, there are small probabilities of upgrades or downgrades to adjacent ratings, and even smaller probabilities of changes to more distant ratings. To give a typical example, an A rated bond might have a 0.05% probability of migrating upward to AAA, a 2.5% probability of migrating to AA, a 90% probability of remaining at A, a 5% probability of being downgraded to BBB, a 0.5% probability of being downgraded to BBB, and very low or negligible probabilities of lower downgrades.

The best-known migration model, the CreditMetrics model, considers the forward value of a loan at the end of the horizon period for each possible end-horizon credit rating: its value if it ends up at AAA, AA, and so forth, down to its value if it defaults, which would also be conditional on recovery rate assumptions [4]. These values are found by discounting the loan's cash flows at a rate equal to the risk-free end-horizon forward rate plus an estimate of the credit spread for that rating. The combination of transition probabilities and end-horizon loan values enables the modeler to apply value-at-risk (VaR) analysis and obtain the credit VaR as the current loan value minus the relevant quantile of the distribution of forward loan values.

In the case of a single loan taken out by a particular obligor, the only transition probabilities needed are those for that obligor's current rating. More generally, calculations for a portfolio of loans would be based on a complete transition matrix: in

the case of the CreditMetrics model, this would be an 8×8 matrix showing the probabilities that any current AAA, AA, A, BBB, BB, B, CCC, and D rating would change to any other.

However, we cannot reasonably expect default and migration probabilities to remain constant over time. There is therefore a need for an underlying structural model that ties these to more fundamental economic variables. CreditMetrics responds to this need by invoking the Merton model and making associated simplifications to obtain these probabilities from the joint distribution of the equity returns of obligor firms. An alternative solution is offered by the CreditPortfolioView model [5, 6]: this model relates these probabilities to macroeconomic variables such as the unemployment rate, the economic growth rate, the level of long-term interest rates, and savings rates. This model therefore captures the notion that the credit cycle closely follows the business cycle – when the economy worsens, both downgrades and defaults increase, and *vice versa*.

However, all these models involve simplistic assumptions of one sort or another and are highly reliant on suitable datasets.

Intensity Models of Default Risk

There are also intensity-based models, sometimes also referred to as reduced-form models. These do not specify the process leading to default, as such; instead, default is modeled as an exogenous process that occurs randomly in accordance with a fitted intensity or hazard function. These models are fundamentally empirical and do not embody any economic theory of default: they make no attempt to relate default risk to capital structure and make no assumptions about the causes of default. To give an illustration, one simple intensity-based model postulates that the observed credit spread (π) is equal to the product of the default probability and the loss given default, *viz*:

$$\pi = PD \times LGD \quad (8)$$

As an aside, one will note that equation (8) is similar to equation (1). However, whereas equation (1) is an exercise under the P measure, equation (8) would be an exercise under the Q measure, because it would be used to back out default probabilities from observed bond prices. Any spread depends on both the maturity

of the loan and the credit rating of the borrower, and is usually observable. The probabilities of default for different maturities and credit ratings can then be recovered if we can estimate or specify the loss given default (or the recovery rate).

Since intensity-based models are based on empirical debt prices, they are able to reflect complex default term structures better than some of the earlier approaches considered. However, corporate bond markets can be rather illiquid, and the pricing data available are often inaccurate. These data problems mean that, even though they are made to fit the available data, we cannot take for granted that fitted intensity models will necessarily provide better estimates of “true” default probabilities than other methods.

Another common type of intensity model postulates an exogenous default process that would be fitted to historical default data. Subject to certain conditions, we can model defaults by a Poisson process. However, a basic Poisson process is unlikely to be accurate because it assumes the default intensity parameter to be constant and we would expect it to be correlated with the credit cycle. To get around this problem, we can model defaults as driven off a Poisson process with a stochastic intensity that takes account of business cycle and other macroeconomic factors that affect it. A good example is the CreditRisk+ model of Credit Suisse Financial Products, which models default rates as functions of gamma-distributed background factors [7]. The CreditRisk+ model is attractive because it yields closed-form solutions for default risks, which are very useful computationally; it is also attractive in so far as the only information it requires for any instrument is information about default rates and exposures.

General Problems and Future Objectives in Default Risk Modeling

While different default risk models have their own characteristic strengths and weaknesses, all models of default risk have generic weaknesses. One weakness is their exposure to model risk: it is often difficult to empirically discriminate between alternative models, so we can never be sure that any model we choose will be the “best” one. This is so even where we are dealing with approaches in which the “model” is

wholly or partially implicit, as is the case with credit ratings: any approach to default risk must be based on at least some assumptions that have to be taken on trust and cannot be tested. However, even within the confines of any given model (or approach), all are subject to parameter risk: there will be certain critical parameters whose values cannot be precisely determined even if we had unlimited amounts of past data. This is because parameters are, in principle, calibrated rather than estimated: even if we had “perfect” parameter estimates based on past data – which is never the case – model calibration requires us to make judgments over the extent to which the values of those same parameters might differ from their estimated historical values. Calibration always requires judgment, which is necessarily subjective and open to error. Furthermore, data are inevitably limited in supply and often flawed in quality, so reliable estimates of “past” parameter values can be difficult to obtain. Evidence also suggests that estimates of default probabilities are likely to be sensitive to the values of key parameters such as volatilities and correlations. Correlations are especially troublesome, not only because data are scarce, but also because the correlations used in practice are obtained using assumptions that are empirically doubtful. Estimates of expected losses on bond portfolios are also likely to be sensitive to the values of these same parameters, as well as to assumptions about recovery rates.

Much more work remains to be done. One major objective of ongoing research is to build models that adequately capture the market risks associated with default-risky positions: most current models of default risk ignore the market risks involved and ignore interactions between market and credit risk factors. Another important objective is to develop default risk models that can provide better valuations of default-risky positions, especially positions in credit derivatives. The explosive growth in the credit derivatives market suggests that practitioners are making good progress in this front. Nonetheless, the development of more sophisticated default risk models will be an important factor in the development of more advanced credit derivatives and in the future growth of the credit derivatives market.

Degradation and Shock Models

Stochastic degradation (*see Common Cause Failure Modeling*) in engineering, ecological, and biological systems is naturally modeled by increasing (decreasing) stochastic processes to be denoted by $W_t, t \geq 0$. We are interested in modeling stochastic degradation as such and in considering the first passage times, when this degradation reaches the predetermined or random level D . The latter interpretation can be useful for risk and safety assessment, when D defines some critical safety region. When, for instance, degradation implies the diminishing resistance to loads in some structures, it can result not just in an “ordinary” failure, but in a severe catastrophic event.

The main focus of this paper is on shock models (*see Nonlife Insurance Markets; Repair, Inspection, and Replacement Models; Mathematics of Risk and Reliability: A Select History*), which, in many instances, form the basis for the corresponding stochastic modeling of degradation. Shocks are generally interpreted as instantaneous harmful random events that represent danger to human beings, the environment, or the economic values. Therefore, probabilistic description of shock processes is important in analysis of different risks.

In the section titled “‘Direct’ Models of Degradation”, some simple models of degradation, not related to shocks, are considered. In the sections titled “Shot-Noise Process” and “Asymptotic Cumulative Shocks Modeling” the cumulated shock models are discussed, and simple asymptotic results are presented. In many applications, the number of shocks in the time interval of interest is large, which makes it possible to apply asymptotic methods rather effectively. In the section titled “Noncumulative Shock Models”, some important noncumulative shock models, especially in safety and risk assessment, are briefly described. The impact of a single (noncumulative) shock can be disastrous or even fatal in some settings, therefore this case needs careful attention. Finally, some weaker criterions of failures or of critical values of deterioration caused by shocks are discussed in the section titled “Weaker Criterions of Failures”.

In this presentation, we try to focus on the meaning of the models and interpretations of results, but the

subject is rather technical and one cannot avoid certain mathematical details.

“Direct” Models of Degradation

In this section we briefly define several approaches that are most often used in engineering practice for degradation modeling. The simplest one that is widely used is the path model, the stochastic nature of which is described either by the additive or by the multiplicative random variable.

$$W_t = \eta(t) + Z \quad (1)$$

$$W_t = \eta(t)Z \quad (2)$$

where $\eta(t)$ is an increasing, continuous function ($\eta(0) = 0, \lim_{t \rightarrow \infty} \eta(t) = \infty$) and Z is a nonnegative random variable with the cumulative distribution function (cdf) $G(z)$. Therefore, the sample paths (realizations) for these models are monotonically increasing. Thus, the “nature” of the stochastic process is simple and meaningful: let the failure (catastrophe) be defined as *reaching* by $W_t, t \geq 0$ the degradation threshold $D > 0$ and T_D be the corresponding time to failure random variable with the cdf $F_D(t)$. It follows, e.g., for model (2) that

$$\begin{aligned} F_D(t) &= \Pr(W_t \geq D) = \Pr\left(Z \geq \frac{D}{\eta(t)}\right) \\ &= 1 - G\left(\frac{D}{\eta(t)}\right) \end{aligned} \quad (3)$$

Example 1 Let $\eta(t) = t$ and assume the Weibull law for Z : $G(z) = 1 - \exp\{-(\lambda z)^k\}$, $\lambda, k > 0$. Then, in accordance with relation (3)

$$F_D(t) = \exp\left\{-\left(\frac{\lambda D}{t}\right)^k\right\} \quad (4)$$

which is often called the *inverse Weibull distribution* [1]. Specifically, when $\lambda = 1, k = 1$,

$$F_D(t) = \exp\left\{-\frac{D}{t}\right\} \quad (5)$$

It is clear that the value at $t = 0$ for this distribution should be understood as

$$F_D(0) = \lim_{t \rightarrow 0} F_D(t) = 0 \quad (6)$$

The inverse-Weibull distribution is a convenient and simple tool for describing threshold models with a linear function $\eta(t)$.

Assume now that the threshold D is a random variable with the cdf $F_0(d) = \Pr(D \leq d)$ and let, at first, degradation be modeled by the deterministic, increasing function $W(t)$ ($W(0) = 0, \lim_{t \rightarrow \infty} W(t) = \infty$). Or, equivalently, the problem can be reformulated in terms of the fixed threshold and random initial value of degradation. Denote by T the random time to failure (degradation reaches the threshold value). As events $T \leq t$ and $W(t)$ are equivalent, similar to equation (3) [2], we have

$$F(t) \equiv \Pr(T \leq t) = \Pr(D \leq W(t)) = F_0(W(t)) \quad (7)$$

where the last equality is owing to the fact that the cdf of D is $F_0(d)$. Substituting d by $W(t)$, finally results in equation (7).

Now, let a deterministic degradation $W(t)$ in equation (7) turn to a stochastic process $W_t, t \geq 0$. To obtain the corresponding distribution of the time to failure, in this case, we must obtain the expectation of $F_0(W_t)$ with respect to the process $W_t, t \geq 0$

$$F(t) = E[F_0(W_t)] \quad (8)$$

This equation is too general, as the stochastic process is not specified. The following example considers the path model for $W_t, t \geq 0$.

Example 2 Let, e.g., $F_0(d) = 1 - \exp\{-\lambda d\}$ and $W_t = \eta(t)Z$, where Z is also exponentially distributed with parameter μ . Direct integration in equation (8) gives

$$\begin{aligned} F(t) &= E[1 - \exp\{-\lambda \eta(t)Z\}] \\ &= \int_0^\infty (1 - \exp\{-\lambda \eta(t)z\}) \mu \exp\{-\mu z\} dz \\ &= 1 - \frac{\mu}{\mu + \lambda \eta(t)} \end{aligned} \quad (9)$$

Probably, the most popular and well investigated stochastic process is the Wiener process (see **Life-time Models and Risk Assessment**). The Wiener process with drift is also often used for modeling wear, although its sample paths are not monotone (but the mean of the process is a monotonically increasing function). It is defined as

$$W_t = \mu t + X(t) \quad (10)$$

where $\mu > 0$ is a drift parameter and $X(t)$ is a standard Wiener process: for the fixed $t \geq 0$ the random variable $X(t)$ is normally distributed with zero mean and variance $\sigma^2 t$. It is well known [3] that the first passage time T_D

$$T_D = \inf_t \{t, W_t > D\} \quad (11)$$

is described in this case by the inverse Gaussian distribution (see **Bonus–Malus Systems**)

$$\begin{aligned} \bar{F}_D(t) &= \Pr(T_D > t) = \Phi\left(\frac{D - \mu t}{\sqrt{t}\sigma}\right) \\ &\quad - \exp\{-2D\mu\} \Phi\left(\frac{D + \mu t}{\sqrt{t}\sigma}\right) \end{aligned} \quad (12)$$

$$E[T_D] = \frac{D}{\mu}, \text{Var}(T_D) = \frac{D\sigma^2}{\mu^3} \quad (13)$$

where $\Phi(t)$, as usual, denotes the cdf of the standard normal random variable.

Another popular process for modeling degradation is the gamma process. Although the estimation of the parameters for the degradation models driven by the gamma process is usually more complicated than for the Wiener process, it better captures the desired monotonicity. The gamma process is a stochastic process $W_t, W_0 = 0$ with independent nonnegative increments having a gamma cdf with identical scale parameter [4]. The increment $W_t - W_\tau$ has a gamma distribution with a shape parameter $v(t) - v(\tau)$ and a scale parameter u , where $v(t)$ is an increasing function and $v(0) = 0$. Therefore, W_t is gamma distributed with a shape parameter $v(t)$ and a scale parameter u and

$$E[W_t] = \frac{v(t)}{u}, \text{Var}(W_t) = \frac{v(t)}{u^2} \quad (14)$$

The first passage time T_D , which for the monotonically increasing processes is just the time of reaching D , is described in this case by the following distribution [5]:

$$F_D(t) = \Pr(T_D \leq t) = \Pr(W_t \geq D) = \frac{\Gamma(v(t), Du)}{\Gamma(v(t))} \quad (15)$$

where $\Gamma(a, x) = \int_x^\infty t^{a-1} e^{-t} dt$ is an incomplete gamma function for $x > 0$. Thus, deterioration, which takes place in accordance with the gamma process, can be effectively modeled in this case.

A natural way of modeling additive degradation is via the sum of random variables, which represent the degradation increments

$$W_t = \sum_{i=1}^n X_i \quad (16)$$

where $X_i, i = 1, 2, \dots, n$ are positive independent and identically distributed (i.i.d.) random variables, with a generic variable denoted by X , and n is an integer.

Example 3 [3] Assume that a mechanical item is employed in a number of operations and each of them increases the item's wear on X units. Assume that X is normally distributed with $E[X] = 9.2$ and $\sqrt{\text{Var}(X)} = 2.8$, which guarantees that for practical reasons this random variable can be considered as a positive one. Let the initial wear be zero. The item is replaced by a new one if the total degree of wear exceeds 1000. What is the probability of replacing the item after 100 operations are performed?

Taking into account the property stating that the sum of n i.i.d. normally distributed random variables is a normally distributed random variable with parameters $nE[X]$ and $\sqrt{\text{Var}(X)n}$, we obtain

$$\begin{aligned} \Pr\left(\sum_{i=1}^{100} X_i \geq 1000\right) &= 1 - \Phi\left(\frac{1000 - 920}{28}\right) \\ &= 1 - \Phi(2.86) = 0.021 \end{aligned} \quad (17)$$

Thus the probability of an item's replacement after 100 cycles is 0.021.

The next step to a more real stochastic modeling is to view n as a random variable N or some point process $N_t, t \geq 0$. The latter is counting point events of interest in $[0, t], t \geq 0$. The result is called the *compound point process*

$$W_t = \sum_{i=1}^{N_t} X_i \quad (18)$$

Denote by $Y_i, i = 1, 2, \dots$ the sequence of inter-arrival times for $N_t, t \geq 0$. If $Y_i, i = 1, 2, \dots$ are i.i.d (and this case will be considered in what follows) with a generic variable Y , then the Wald's equation [3] immediately yields

$$E[W_t] = E[N_t]E[X] \quad (19)$$

where, specifically for the compound Poisson process with rate m , $E[N_t] = mt$. It can be shown [6] that under certain assumptions, the stationary gamma process ($v(t) = vt$) can be viewed as a limit of a specially constructed compound Poisson process. An important modification of equation (18) of the next section surprisingly results in the fact that the limiting distribution of W_t is gamma with a shape parameter, which already does not depend on t .

Relation (18) has a meaningful interpretation via the shocks – instantaneous external events causing random amount of damage (degradation) $X_i, i = 1, 2, \dots$ and eventually resulting in an accumulated damage W_t . Numerous shock models were considered in the literature (see [7] and references therein). Apart from degradation modeling in various applications, shock models also present a convenient tool for analyzing certain nonparametric properties of distributions [8]. The explicit expressions for W_t usually cannot be obtained. Some results in terms of the corresponding Laplace transforms can be found in [9–11], but effective asymptotic results exist and will be discussed in the section titled “Asymptotic Cumulative Shocks Modeling”.

Shot-Noise Process

A meaningful modification of the cumulative shock model (18) is given by the shot-noise process [12, 13]. In this model, the additive input of a shock of magnitude X_i in $[t, t + dt]$ in the cumulative damage W_t is decreased in accordance with some decreasing (nonincreasing) response function $h(t - s)$. Therefore, it is defined as

$$W_t = \sum_{i=1}^{N_t} X_i h(t - \tau_i) \quad (20)$$

where $\tau_1 < \tau_2 < \tau_3, \dots$ is the sequence of the corresponding arrival (waiting) times in the point process. This setting has a lot of applications in electrical engineering, materials science, health sciences, risk, and safety analysis. For instance, cracks due to fatigue in some materials tend to close up after the material has borne a load that has caused the cracks to grow. Another example is the human heart muscle's tendency to heal after a heart attack [14]. Thus the inputs of shocks in accumulative damage decreases with time.

Equivalently, definition (20) can be written as

$$W_t = \int_0^t Xh(t-u) dN_u \quad (21)$$

where $dN_u = N(t, t+du)$ denotes the number of shocks in $[t, t+dt)$. Firstly, we are interested in the mean of this process. As $X_i, i = 1, 2, \dots$ are independent from the point process $N_t, t \geq 0$ and assuming that $E[X] < \infty$

$$\begin{aligned} E[W_t] &= E[X] \int_0^t h(t-u) dN_u \\ &= E[X] \int_0^t h(t-u)m(u) du \end{aligned} \quad (22)$$

where $m(u) = dE[N_u]/du$ is the rate (intensity) of the point process. For the Poisson process, $m(u) = m$ and

$$E[W_t] = mE[X] \int_0^t h(u) du \quad (23)$$

Therefore, distinct from equation (19), asymptotically the mean accumulative damage is finite, when the response function has a finite integral

$$\lim_{t \rightarrow \infty} E[W_t] < \infty \text{ if } \int_0^\infty h(u) du < \infty \quad (24)$$

which has an important meaning in different engineering and biological applications. It can be shown directly from definitions that, if $E[X^2] < \infty$,

$$\begin{aligned} \text{Cov}(W_{t_1}, W_{t_2}) &= mE[X^2] \int_0^{t_1} h(t_1-u)h(t_2-u) du; \\ &\quad t_1 \geq t_2 \end{aligned} \quad (25)$$

The central limit theorem also takes place for sufficiently large m in the following form [15, 16]:

$$\frac{W_t - E[W_t]}{(\text{Var}(W_t))^{1/2}} \xrightarrow{D} N(0, 1), t \rightarrow \infty \quad (26)$$

where the sign “ D ” means convergence in distribution and, as always, $N(0, 1)$ denotes the standard normal distribution. The renewal case gives similar results.

$$\lim_{t \rightarrow \infty} E[W_t] = \frac{1}{E[X]} \int_0^\infty h(u) du \quad (27)$$

Example 4 Consider a specific exponential case of the response function $h(u)$ and the Poisson process of shocks with rate m

$$W_t = \sum_{i=1}^{N_t} X_i \exp\{\alpha(t - \tau_i)\} \quad (28)$$

By straightforward calculations, [12] using the technique of moment generating functions, it can be shown that for t sufficiently large the stationary value W_∞ has a gamma distribution with mean $m/\lambda\alpha$ and variance $m/\lambda^2\alpha$

$$F_D(t) = \Pr(T_D \leq t) = \Pr(W_t \geq D) = \frac{\Gamma(m/\alpha, D\lambda)}{\Gamma(m/\alpha)} \quad (29)$$

It is well known from the properties of the gamma distribution that as m/λ increases, it converges to the normal distribution, therefore there is no contradiction between this result and asymptotic relation (26).

Asymptotic Cumulative Shocks Modeling

In many applications, the number of shocks in the time interval of interest is large, which makes it possible to apply asymptotic methods. As already stated, exact nonasymptotic results in shocks modeling exist only for the simplified settings. Therefore, the importance of asymptotic methods should not be underestimated, as they usually present, in practice, simple and convenient relations.

The results of this section are based on the methodology of renewal processes, marked point processes, and random walks, but technical details will be skipped (the reader is referred to the corresponding references) and the focus will be on final asymptotic relations. As in the section titled “‘Direct’ Models of Degradation”, consider a family of nonnegative, i.i.d., two-dimensional random vectors $\{(X_i, Y_i), i \geq 0\}$, $X_0 = 0, Y_0 = 0$, where $\sum_{i=1}^n X_i$ is the accumulated damage after n shocks and $Y_i, i = 1, 2, \dots$ the sequence of the i.i.d. interarrival times for the renewal process. Recall that the renewal process is defined by the sequence of the i.i.d. interarrival times. Specifically, when these times are exponentially distributed, the renewal process reduces to the Poisson one. We shall assume for simplicity that X and Y are independent, although the case of dependent variables can be also considered [7]. Let $0 < E[X], E[Y] < \infty, 0 <$

$\text{Var}(X), \text{Var}(Y) < \infty$. It follows immediately from equation (19) and the elementary renewal theorem [3] that

$$\lim_{t \rightarrow \infty} \frac{E[W_t]}{t} = \lim_{t \rightarrow \infty} \frac{E[N_t]E[X]}{t} = \frac{E[X]}{E[Y]} \quad (30)$$

The corresponding central limit theorem can be proved using the theory of stopped random walks [7]

$$\frac{W_t - (E[X]/E[Y])t}{(E[Y])^{-3/2}\sigma t^{1/2}} \longrightarrow N(0, 1), \quad t \rightarrow \infty \quad (31)$$

where $\sigma = \sqrt{\text{Var}(E[Y]X - E[X]Y)}$.

The important relation (31) means that for large t the random variable W_t is approximately normally distributed with expected value $(E[X]/E[Y])t$ and variance $(E[Y])^{-3}\sigma^2(E[X])^2t$. Therefore, only $E[X]$, $E[Y]$, and σ should be known for the corresponding asymptotic analysis, which is very convenient, in practice.

Similar to equation (30),

$$\lim_{t \rightarrow \infty} \frac{E[T_D]}{D} = \lim_{D \rightarrow \infty} \frac{E[N_D]E[Y]}{D} = \frac{E[Y]}{E[X]} \quad (32)$$

where N_D denotes the random number of shocks to reach the cumulative value D . Equation (31) can be now written for the distribution of the first passage time T_D [7] as under:

$$\frac{T_D - (E[Y]/E[X])D}{(E[X])^{-3/2}\sigma D^{1/2}} \longrightarrow N(0, 1), \quad D \longrightarrow \infty \quad (33)$$

This equation implies that for large threshold D the random variable T_D has approximately a normal distribution with expected value $(E[Y]/E[X])D$ and variance $(E[X])^{-3}\sigma^2D$. Therefore, the results of this section can be easily and effectively used in safety and reliability analysis.

We apply equation (33) to the setting of Example 3 [3]. We additionally assume that $E[Y] = 6$ and $\sqrt{\text{Var}(Y)} = 2$ (in hours). The parameter σ in this case is 0.0024916. The question is, what is the probability that a nominal value of 1000 is only exceeded after 600 h? Applying equation (33) we have

$$\begin{aligned} \Pr(T_{1000} \geq 600) \\ &= 1 - \Phi \left(\frac{600 - \frac{6}{9.2} 10^3}{(9.2)^{-3/2} \cdot 24.916 \cdot \sqrt{0.1}} \right) \\ &= 1 - \Phi(-1.848) = 0.967 \end{aligned} \quad (34)$$

Noncumulative Shock Models

Let the shocks occur in accordance with a renewal process or a nonhomogeneous Poisson process. Each shock, independently of the previous history, leads to a system failure with probability θ , and is survived with a complementary probability $\bar{\theta}$. Assume that a shock is the only cause of the system's failure. We see that there is no accumulation of damage and the fatal damage can be a consequence of a single shock. A number of problems in reliability, risk, and safety analysis can be interpreted by means of this model. Sometimes, this setting is referred to as an *extreme shock model* [7].

Let, as previously, $\{Y_i\}_{i \geq 1}$ denote the sequence of i.i.d. lifetime random variables with a generic cdf $F(t)$, and let B be a geometric variable with parameter θ and $S(t, \theta) \equiv \Pr\{T \leq t\}$ denote the probability of the system's failure in $[0, t]$ (the cdf of T). Straightforward reasoning results in the infinite sum for this probability of interest

$$S(t, \theta) = \theta \sum_{k=1}^{\infty} \bar{\theta}^{k-1} F^{(k)}(t) \quad (35)$$

where $F^{(k)}(t)$ is a k -fold convolution of $F(t)$ with itself.

Special complicated numerical methods should be used for obtaining $S(t, \theta)$ in the form of equation (35). Hence, it is very important, for practical assessment of safety or reliability, to obtain simple approximations and bounds. It is well known (see, e.g. [17]) that, as $\theta \rightarrow 0$, the following convergence in distribution takes place:

$$S(t, \theta) \rightarrow 1 - \exp \left\{ -\frac{\theta t}{E[Y]} \right\}, \quad \forall t \in (0, \infty) \quad (36)$$

Specifically, when $\{Y_i\}_{i \geq 1}$ is a sequence of exponentially distributed random variables with constant failure rate λ , equation (36) turns into an exact relation

$$S(t, \theta) = 1 - \exp\{-\theta\lambda t\} \quad (37)$$

Thus, equation (36) constitutes a very simple asymptotic exponential approximation. In practice, the parameter θ is not usually sufficiently small for using approximation effectively (equation (36)), therefore the corresponding bounds for $S(t, \theta)$ can be very helpful.

The simplest (but rather crude) bound that is useful, in practice, for the survival function (see **Insurance Applications of Life Tables; Risk Classification/Life**) $\bar{S}(t, \theta) \equiv 1 - S(t, \theta)$ can be based on the following identity:

$$E[\bar{\theta}^{N_t}] = \sum_{k=0}^{\infty} \bar{\theta}^k (F^{(k)}(t) - F^{(k+1)}(t)) = \bar{S}(t, \theta) \quad (38)$$

Finally, using Jensen's inequality, we have

$$\bar{S}(t, \theta) = E[\bar{\theta}^{N_t}] \geq \bar{\theta}^{E[N_t]} \quad (39)$$

Let $\{Y_n\}_{n \geq 1}$, now, be a sequence of interarrival times for the nonhomogeneous Poisson process with rate $\lambda(t)$. Thus, given a realization $\sum_1^k Y_i = y$, $k = 1, 2, \dots$, the interarrival time Y_{k+1} has the following distribution:

$$F(t|y) = 1 - \frac{\bar{F}(t+y)}{\bar{F}(y)} \quad (40)$$

Similar to equation (35), consider the following geometric-type sum:

$$S_P(t, \theta) = \Pr\{T \leq t\} = \theta \sum_{k=1}^{\infty} \bar{\theta}^{k-1} F_P^{(k)}(t) \quad (41)$$

where $F_P^{(k)}$ denotes the cdf of $\sum_1^k Y_i$ and the subindex "P" stands for "Poisson".

It turns out [18], that, in this case, the cdf $S_P(t, \theta)$ can be obtained exactly in a very simple form, even for the time dependent $\theta(t)$. Let $\lambda(t, H_t)$ denote the complete intensity function for some general orderly point process [19], where H_t is a history of the process up to time t . Conditional rate of termination $\lambda_c(t, H_t)$, which is, in fact, a conditional failure rate for the lifetime T , can be defined *via* the following equation:

$$\begin{aligned} \lambda_c(t, H_t) dt &= \Pr\{T \in [t, t + dt) | H_t, T(H_t) \geq t\} \\ &= \theta(t) \lambda(t, H_t) dt \end{aligned} \quad (42)$$

The condition $T(H_t) \geq t$ means that all shocks in $[0, t)$ were survived. At the same time, it is clear that for the specific case of the Poisson process of shocks equation (42) becomes

$$\lambda_c(t, H_t) = \theta(t) \lambda(t) \quad (43)$$

and eventually, we arrive at a simple exponential representation.

$$S_P(t, \theta(t)) = 1 - \exp \left\{ - \int_0^t \theta(u) \lambda(u) du \right\} \quad (44)$$

Thus $\theta(t) \lambda(t) \equiv r(t)$ is a failure rate for our lifetime T , in this setting.

Weaker Criteria of Failures

In the previous section, the system could be killed by a shock, and it was assumed to be "as good as old", if a shock was survived. Assume that we are looking now at the process of nonkilling shocks, but a failure of a system can still occur when the shocks are "too close" and the system had not recovered from the consequences of a previous shock. Therefore, the time for recovering should be taken into account. It is natural to assume that it is a random variable τ with a cdf $R(t)$. Thus, if the shock occurs while the system still had not recovered from the previous one, then a failure (disaster, catastrophe) occurs. As previously, for the Poisson process of shocks with rate $\lambda(t)$, we want to obtain the probability of a failure-free performance in $[0, t)$, $\bar{S}_P(t)$. Consider the following integral equation for $\bar{S}_P(t)$ [20]:

$$\begin{aligned} \bar{S}_P(t) &= \exp \left\{ - \int_0^t \lambda(u) du \right\} \left(1 + \int_0^t \lambda(u) du \right) \\ &+ \int_0^t \lambda(x) \exp \left\{ - \int_0^x \lambda(u) du \right\} \left[\int_0^{t-x} \lambda(y) \right. \\ &\times \exp \left\{ - \int_0^y \lambda(u) du \right\} R(y) \hat{S}(t-x-y) dy \left. \right] dx \end{aligned} \quad (45)$$

where the first term in the right-hand side is the probability that there was not more than one shock in $[0, t)$ and the integrand defines the joint probability of the following events:

- the first shock occurred in $[x, x + dx)$
- the second shock occurred in $[x + y, x + y + dy)$
- the time between two shocks y is sufficient for recovering (probability $R(y)$)
- the system is functioning without failures in $[x + y, t)$.

By $\hat{S}(t)$ in equation (45), we denote the probability of system's functioning without failures in $[0, t)$, given that the first shock had occurred at $t = 0$. Similar to equation (45)

$$\begin{aligned} \hat{S}(t) = & \exp \left\{ - \int_0^t \lambda(u) du \right\} + \int_0^t \lambda(x) \\ & \times \exp \left\{ - \int_0^x \lambda(u) du \right\} R(x) \hat{S}(t-x) dx \end{aligned} \quad (46)$$

Simultaneous equations (45) and (46) can be solved numerically. On the other hand, for the constant failure rate λ , these equations can be easily solved *via* the Laplace transform. Obtaining the Laplace transform of $\hat{S}(t)$ for this specific case from equation (46), we finally arrive at

$$\tilde{\bar{S}}_P(s) = \frac{s[1 - \lambda \tilde{R}(s + \lambda)] - \lambda^2 \tilde{R}(s + \lambda) + 2\lambda}{(s + \lambda)^2 [1 - \lambda \tilde{R}(s + \lambda)]} \quad (47)$$

where $\tilde{\bar{S}}_P(s)$ and $\tilde{R}(s)$ denote Laplace transforms of $\bar{S}_P(t)$ and $R(t)$, respectively.

Example 5 Exponentially distributed $\tau : R(t) = 1 - \exp\{-\mu t\}$. Then

$$\tilde{R}(s + \lambda) = \frac{\mu}{(s + \lambda)(s + \lambda + \mu)} \quad (48)$$

and

$$\tilde{\bar{S}}_P(s) = \frac{s + 2\lambda + \mu}{s^2 + s(2\lambda + \mu) + \lambda^2} \quad (49)$$

Performing the inverse Laplace transform

$$\bar{S}_P(t) = A_1 \exp\{s_1 t\} + A_2 \exp\{s_2 t\} \quad (50)$$

where s_1, s_2 are the roots of the denominator in equation (49) and are given by

$$s_{1,2} = \frac{-(2\lambda + \mu) \pm \sqrt{(2\lambda + \mu)^2 - 4\lambda^2}}{2} \quad (51)$$

and

$$A_1 = \frac{s_1 + 2\lambda + \mu}{s_1 - s_2}, A_2 = -\frac{s_2 + 2\lambda + \mu}{s_1 - s_2} \quad (52)$$

Equation (50) gives an exact solution for $\bar{S}_P(t)$. In applications, it is convenient to use simple

approximate formulas. Consider the following reasonable assumption

$$\frac{1}{\lambda} \gg \bar{\tau} \equiv \int_0^\infty (1 - R(x)) dx \quad (53)$$

Relation (53) means that the mean interarrival time in the shock process is much larger than the mean time of recovery, and this is often the case, in practice. In the study of repairable systems, the similar case is usually called the *fast repair*. Therefore, using this assumption, equation (50) results in the following approximate relation:

$$\bar{S}_P(t) \approx \exp\{-\lambda^2 \bar{\tau} t\} \quad (54)$$

Assume now that time of recovery for the homogeneous Poisson process of shocks is a constant τ . In this case, straightforward reasoning defines the probability of survival as the following sum:

$$\bar{S}_P(t) = \exp\{-\lambda t\} \sum_{k=0}^{[t/\tau]} \frac{(\lambda(t - (k-1)\tau))^k}{k!} \quad (55)$$

where notation $[\cdot]$ means the integer part.

Another possible generalization of the shock models is to consider two independent shock processes: the process of harmful shocks with rate λ_h and the process of healing (repair) shocks with rate λ_r . A system fails if we have two successive harmful shocks, but if a harmful shock is followed by a healing one, it is not a failure. In fact, mathematically, the problem can be described by the equations similar to (45–46) and solved *via* the Laplace transform. Similar to equation (54), the fast repair approximation, in this case, is given by

$$\bar{S}_P(t) \approx \exp \left\{ - \frac{\lambda_h^2}{\lambda_h + \lambda_r} t \right\} \quad (56)$$

which is a simple and effective approximation formula.

MAXIM FINKELSTEIN

Dependent Insurance Risks

The financial consequences of insurance contracts are uncertain (risky), simply due to their contingent nature; that is, exchanges of money, such as benefit payments and sometimes premiums, are based upon unforeseen, contingent events. Practical insurance contracts are complex and span many dimensions, including the number of risks covered, types of coverages, and payment structure. Because of these many dimensions, it is helpful to understand their interrelationships and how different aspects of a risk may be dependent. Further, from an insurer's viewpoint, diversification of risks is at the heart of risk pooling, a fundamental risk management mechanism. The success of diversification depends on the dependencies among insurance risks in an insurer's portfolio.

Actuaries and other financial analysts generally use the language of probability to assess uncertainty associated with insurance contracts. This article follows this paradigm and uses the idea of random variables (or collections of random variables, stochastic processes) to represent uncertain outcomes associated with insurance contracts. Dependencies among insurance risks can naturally be represented using ideas of dependencies among random variables. This article explores these concepts in the context of actuarial and insurance risks.

What Are Insurance Risks?

Because of the many dimensions of an insurance risk, it is useful to discuss types of dependencies in terms of categories of insurance risks. As with supply and demand in economics, insurance risks are represented on an individual and a collective basis. The former is known as an *individual risk model*, a "micro" representation of an individual contract. The latter is known as a *collective risk model*, a "macro" representation of a portfolio, or collection of contracts.

It is also useful to think of insurance coverages in terms of the length of the contract. Contracts with long-term coverages include most life, annuity, and retirement systems policies. Here, the time of the benefit payment, and for some contracts the

amounts of payment, often depends on the length of the survival time of the insured. Because of the potentially long length of time between payments and the occurrence of an insured event, present values are critical for valuing long-term contracts. In contrast, most individual property/casualty, health, and group policies can be thought of as "short-term" coverages. They are characterized by the reduced role of present values. In addition, the benefit amount is typically a random variable. Its value will depend in health insurance on the services provided, and in property insurance on the extent of the property damage.

Why Is Dependence Important?

The degree of dependence impacts insurance risk measures that are used to guide enterprises that manage these risks. Two broad classes of summary measures are those that (1) quantify the *financial solvency* (see **Solvency**) of a firm and (2) those for valuation of insurance contracts (see **Fair Value of Insurance Liabilities**). The latter class is further subdivided into (a) valuation at contract initiation, the pricing function, and (b) valuation following contract initiation, the liability or reserving function. Financial solvency measures are analyzed from an insurer's viewpoint and so dependencies among portfolios of insurance risks take precedence. Epidemics, floods, and earthquakes are risks that are pandemic or widespread risks that may influence many contracts within an insurer's portfolio, thus inducing dependencies. The capital investment environment is another example of a pandemic risk where an upturn or downturn in returns from capital investments affects the value of all contracts in a portfolio simultaneously, thus inducing dependencies. From an insurer's viewpoint, relationships among different categories of insurance, also known as *lines of business*, are also critical for establishing capital adequacy standards. Many lines of business are positively related, often due to a common economic environment that they share. Insurers often seek lines of business that are negatively related, which is useful for diversification of risks. For example, improving mortality may induce lower claims for life insurance and more claims for annuities.

Individual insurance contracts span many dimensions, they may: (a) cover more than a single person, structure or firm, (b) provide benefits that vary over

different types of claims, (c) provide benefits that vary by the cause of a claim, and (d) provide benefit payments immediately as well as over a longer period of time. For the first dimension, in annuities and life insurance, benefit payments are determined based on the survival of two or more covered lives. Intuitively, pairs of individuals exhibit dependence in mortality because they share common risk factors. These factors may be purely genetic, as in the case of a grandparent and grandchild, or environmental, as in the case of a married couple. In automobile insurance, one may vary the amount of coverage based on the type of claim such as damage to the automobile or injury to a third party. It seems intuitively plausible that a more serious accident will induce larger claims for both types of coverages, inducing a dependency among claim types. In pensions associated with an individual's employment, a person may leave employment owing to disability, voluntary or involuntary separation from work or permanent retirement from the labor force. A poor economy can increase each of these three causes of leaving employment, thus inducing a dependency among the causes of exiting. This is important from an insurer's viewpoint because each cause will mean a different benefit payment.

Statistical Models of Dependence

There are several approaches for quantifying relationships among random variables. The goal of each method is to understand the joint distribution function of random variables; distribution functions provide all the details on the possible outcomes of random variables, both in isolation of one another and as they occur jointly. We categorize these methods as (a) a "variables-in-common", (b) a conditioning, and (c) a direct approach. As we will see, there is substantial overlap in these approaches in that multivariate distributions for modeling dependencies can be derived using more than one approach.

In insurance, the "variables-in-common" technique is used extensively for generating dependent random variables. With this technique, a common element serves to induce dependencies among several random variables. One way to induce a dependency is through a latent (unobserved) variable that is common to all random variables. For example, we might assume that Y_1 and Y_2 are two independent (underlying) lifetimes, that Z represents the

time until a common disaster (such as an epidemic, earthquake, or flood) and that $X_1 = \min(Y_1, Z)$ and $X_2 = \min(Y_2, Z)$ are observed lifetimes. The common latent variable Z induces a dependency between X_1 and X_2 . For example, for further discussions of this "joint-life" mortality structure and its relevance to life insurance pricing, see [1]. More generally, one might assume that the distribution functions of X_1 and X_2 each depend on a latent variable Z and that, conditional on Z , the distribution functions are independent. For example, given Z , assume that X_1 and X_2 have independent exponential distributions with mean $1/Z$. Then, if Z has a gamma distribution, it is straightforward to show (unconditionally) that X_1 and X_2 have a bivariate Pareto distribution.

Another common method of modeling dependent distributions is to use conditioning arguments. That is, if one is interested in the joint distribution of X_1 and X_2 , one specifies the marginal distribution of X_1 and the conditional distribution of X_2 , given X_1 . Regression analysis can be viewed as a type of modeling based on conditional distributions. In regression, it is customary to identify a variable of interest, such as claim size, and model its distribution conditional on other variables, such as policyholder characteristics including age, gender, driving experience, and so forth. Based on the number of applications, regression analysis is probably the most widely used applied statistical method in the social sciences, including insurance. As another example, many models in time series analysis rely on conditional distributions. For example, we could think of X_2 as the current value of a series and X_1 as the prior value of the same series. Then, the distribution of X_2 given X_1 is a Markovian model of a time series.

A third approach is to directly model the joint distribution of a collection of random variables. In terms of prevalence of applications, the normal distribution is by far the most widely used multivariate distribution. Other multivariate distributions have found their way into applications but are used much less frequently. These include the multivariate t -, Pareto, and Poisson distributions.

In insurance, it has become common to use "*copula*" models (see **Copulas and Other Measures of Dependency**) to represent dependence. To define a copula, begin by considering " p " uniform (on the unit interval) random variables, $U_1, \dots, U_p$. Assume that $U_1, \dots, U_p$ may be related through their joint

distribution function

$$\Pr(U_1 \leq u_1, \dots, U_p \leq u_p) = C(u_1, \dots, u_p) \quad (1)$$

Here, we call the function C a *copula*. Further, U is a (*ex ante*) uniform random variable whereas, u is the corresponding (*ex post*) realization. To complete the construction, we may select arbitrary marginal distribution functions $F_1(x_1), \dots, F_p(x_p)$. Then, the function

$$C(F_1(x_1), \dots, F_p(x_p)) = F(x_1, \dots, x_p) \quad (2)$$

defines a multivariate distribution function, evaluated at $(x_1, \dots, x_p)$, with marginal distributions $F_1, \dots, F_p$. Compared to the classic multivariate distribution approach, the primary advantage of using copulas is that one can use different marginal distributions. Thus, for example, one might use a short- or medium-tail distribution such as a gamma for the first marginal distribution for automobile damage. A longer tail distribution, such as a Pareto, could be used for the second distribution, which represents injury claims. See, for example [2] or [3] for more information on copulas.

Actuarial Applications of Dependence Modeling

Having described types of risks and their importance in practice as well as approaches to modeling dependence, we are now in a position to describe specific models of dependence used in actuarial and insurance models. This list is necessarily incomplete and is the subject of vigorous ongoing research.

Tabular Summaries of Insurance Risks. It is customary in mortality to present tabular information by age and gender, as well as by the time since purchasing insurance (known as a *select* and *ultimate decomposition*), size of the insurance benefit, and so forth. As another example, rating tables in automobile insurance are typically presented based on age, gender, type of driving (work *versus* pleasure), average amount of driving, and so forth. These traditional risk tables summarize an average risk by one or more factors of interest. Although this approach is limited (only averages are portrayed, only information by factors portrayed is available), it also clearly indicates a long-standing interest in actuarial studies in dependence modeling.

Linear Regression Studies. Risk tables are often created using more formal statistical methods such as linear regression. Linear regression is a widely used tool in statistical modeling. It provides a disciplined approach for deciding which combinations of factors are important determinants of a risk. The goal of this methodology is to estimate a regression function, which is a conditional mean of the risk given the rating factors. Thus, although certainly more flexible than simple risk tables, it focuses on only one aspect of a conditional distribution, the mean.

Other (Nonlinear) Regression Methods. When the underlying risk is not approximately normally distributed, other types of nonlinear regression models can be used to study insurance data. In *mortality studies*, it is customary to use survival models that incorporate special long-tail and censored features of lifetime data. In studying frequencies of accident claims, count regressions are employed, typically using Bernoulli, Poisson, and negative binomial distributions. For studying claim severities, medium-tail distributions such as the gamma are employed. For the analyst, a convenient fact is that Bernoulli, Poisson, negative binomial, and gamma regressions are special cases of the generalized linear model family of regression routines (see, for example [4]). For univariate risks that appear over time, such as interest rates and inflation, time series regression models are used to forecast future values and for *stochastic control* in insurance (see **Stochastic Control for Insurance Companies**). For risks that are observed both over time and in the cross section, longitudinal/panel data models are of interest. For example, we might have workers' compensation claims from a cross section of small firms, observed over 5–10 years. In this regard, panel data methods have been shown to be desirable statistical techniques as well as produce desirable *credibility estimates*. Panel data methods are often used to study insurance corporate behavior, by examining cross sections of firms over time.

Dependence between Frequency and Severity. In regression studies, one focuses on a single risk as the primary measure of interest and uses other factors to explain or predict this risk. When considering the number of claims (frequency) and the amount of claims (severity), there are two measures of interest suggesting the use of a bivariate risk measure. However, the relationship between these

two measures is hierarchical, in the sense that one typically first considers the number of claims and then, conditional on the number, the claims amount is considered. This is the traditional *collective risk model* (see **Collective Risk Models**). Thus, even the dimension of the claim vector is dependent on the frequency. It is traditional to first condition on the claims number and to then assume that the claims severity marginal distribution does not depend on the frequency. Specifically, suppose that N is the claims number random variable and $C_1, \dots, C_N$ are the corresponding claim amounts. Then, one models the joint distribution of $(N, C_1, \dots, C_N)$ as the marginal frequency distribution times the conditional distribution of severity, given frequency,

$$\begin{aligned} f(N = n, C_1, \dots, C_N) &= f(N = n) \\ &\quad \times f(C_1, \dots, C_N | N = n) \\ &= f(N = n) \\ &\quad \times \prod_{i=1}^n f(C_i | N = n) \quad (3) \end{aligned}$$

It is customary to assume that the conditional distribution of severity, given frequency $f(C_i | N = n)$ does not depend on frequency.

Other Multivariate Dependencies. In other actuarial applications, there are many examples where this natural hierarchy does not exist and more general dependence structures are useful. We have already discussed the case where more than one life is involved in an insurance contract. Modeling the dependence among lives can either be done using “variables-in-common” techniques or a copula approach. Similarly, modeling dependence among causes of failure can be analyzed using these techniques. However, it is probably fair to say that dependence causes are more commonly analyzed using *multistate models in life insurance mathematics*.

Particularly in property and casualty insurance, it is common for an event to trigger several types of claims under contract. For example, in automobile insurance, an accident may cause damage to one’s own vehicle, damage to another motorist’s vehicle, as well as injury to the drivers. More severe accidents

will cause each of these three types of claims to be larger, inducing a dependency among them. Because injury types of claims tend to be longer tailed compared to vehicle damage claim types, it is natural to use a copula approach to model the dependency yet using different marginal distributions for each claim type.

When examining portfolios of insurance contracts broken down by line of business, the statistical model framework is similar. Some lines of business have relatively short tails (term *life insurance*) whereas, others have long tails (medical malpractice insurance) and thus it is desirable to allow each line of business to have its own marginal distribution. However, there are often relationships among these lines due to a common corporate structure (marketing, underwriting, and so forth) and thus it is important to understand their dependence. The copula approach is becoming the favored approach for this type of analysis.

Concluding Remarks

Concepts of dependence are critical to almost every mathematical and probabilistic model of insurance operations. In this article, we have sought to introduce the concepts that are most directly related to widely known statistical methods. Concepts of dependence also take on critical roles in other actuarial and insurance models including those of *stochastic ordering of risks*, *comonotonic risks* (see **Comonotonicity**), neural nets, fuzzy set theory, and others.

Design of Reliability Tests

What are Reliability Tests?

Reliability tests provide the theoretical and practical tools whereby it can be ascertained that the probability and capability of components, products, and systems to perform their required functions in specified environments for the desired function period without failure or the desired and specified reliability and life have indeed been designed and manufactured in them [1].

It is very essential that for any industry and technology to be competitive, in today's highly competitive world marketplace, all companies have to know the reliability of their products, have to be able to control it, and have to produce them at the optimum reliability level (*see* **Reliability Optimization; Quantitative Reliability Assessment of Electricity Supply**) that yields the minimum life-cycle cost (*see* **Repair, Inspection, and Replacement Models; Reliability Integrated Engineering Using Physics of Failure**) to the user. How to design and apply reliability tests (*see* **Reliability of Consumer Goods with "Fast Turn Around"; Hazard and Hazard Ratio**) in industry is a very fast growing and very important field in consumer and capital goods industries, in space and defense industries, and in National Aeronautics and Space Administration (NASA) and Department of Defense (DoD) agencies.

Reliability Test Objectives

The general goal of reliability tests is to determine if the performance of components, equipment, and systems, either under closely controlled and known stress conditions (*see* **History and Examples of Environmental Justice; Reliability Demonstration; Stress Screening**) in a testing laboratory or under field use conditions, with or without corrective and preventive maintenance, and with known operating procedures, is within specifications for the desired function period, and if it is not, whether it is the result of a malfunction or of a failure that requires corrective action. To achieve this goal, tests are done to determine the failure rate, the mean life, and the reliability of components, equipment, and systems and their associated confidence limits at desired confidence levels. On the

basis of the results obtained, the next step is to determine the pattern of recurring failures, the causes of failures, the underlying times-to-failure distribution, and the associated stress levels. Thus we can provide guidelines as to whether corrective actions should be taken and what these should be. Next the reliability test is repeated to provide reevaluation of the reliability wise performance of the units after corrective actions are taken to assure that these actions are the correct ones and are as effective as intended.

In some cases where high reliability is required after a certain development period, i.e., designing the spacecraft in the Apollo Project, it is required to determine the growth in the mean life and/or the reliability of units during their research, engineering, and development phase; and whether the growth rate is sufficient to meet the mean life and/or the reliability requirements of the specifications by the time the life and/or the reliability need to be demonstrated.

Another important goal of reliability tests is to provide management with the reliability test results so that the requested information is presented in a very easily understood form throughout the complete evaluation of a component, equipment, or system, to appreciate the value of the reliability testing efforts and make the right decisions for the improvement of the mean time between failures (MTBFs) (*see* **Reliability Growth Testing; Availability and Maintainability**), failure rate, and/or the reliability of company products.

Reliability Test Types

Developmental testing occurs during the early phases of the product's life cycle, usually from project inception to product design release to manufacturing. It is vital to be able to characterize the reliability of the product as it progresses through its initial design stages so that the reliability specifications will be met by the time the product is ready to be released to production. With a multitude of design stages and changes that could affect the product's reliability, it is necessary to closely monitor how the product's reliability grows and changes as the product's design matures. There are a number of different test types during this phase of a product's life cycle to provide useful reliability information [2–4]:

1. Component-level testing (see Enterprise Risk Management (ERM); Expert Judgment; No Fault Found; Probabilistic Risk Assessment)

Although component-level testing can continue throughout the development phase of a product, it is most likely to occur very early in the process. This may be owing to the unavailability of parts in the early stages of the development program. There may also be a special interest in the performance of a specific component if it has been radically redesigned or if there is a separate or individual reliability specification for that component. In many cases, component-level testing is undertaken to begin characterizing a product's reliability even though full system-level test units are unavailable or prohibitively expensive. The system-level reliability can be modeled on the basis of the configuration of the components and the result of component reliability testing, if sufficient understanding exists to characterize the interaction of the components.

2. System-level testing

Although the results of component-level tests can be used to characterize the reliability of the entire system, the ideal approach is to test the entire system, particularly if that is how the reliability is specified. Although early system-level test units may be difficult to obtain, it is advisable to perform reliability tests at the system level as early in the development process as possible. At the very least, comprehensive system-level testing should be performed immediately prior to the product's release for manufacturing in order to verify the designed-in reliability. During such system-level reliability testing, the units under test should be from a homogeneous population and should be devoted solely to the specific reliability test.

3. Environmental testing (see Statistics for Environmental Toxicity; Low-Dose Extrapolation; Meta-Analysis in Nonclinical Risk Assessment)

It may be necessary in some cases to institute a series of tests in which the system is tested at extreme environmental conditions or with other stress factors accelerated above the normal levels of use. Environmental testing is performed over a wide range of environments such as temperature, pressure, humidity, and outdoor or indoor conditions.

4. Accelerated testing (see Reliability Demonstration; Lifetime Models and Risk Assessment; Mathematics of Risk and Reliability: A Select History; Hazard and Hazard Ratio)

It is used to determine the ability of components, equipment, or systems to withstand stresses much higher than would be expected under actual operating conditions [3]. It may be that the product would not normally fail within the time constraints of the test and, in order to get meaningful data within a reasonable time, the stress factors must be accelerated. Failure rates, mean lives, or reliabilities are obtained at four or five accelerated stress levels, and are then extrapolated to those at actual operating, or derated, stress levels or conditions.

5. Manufacturing testing (see Product Risk Management: Testing and Warranties; Reliability Growth Testing)

This testing takes place after a product's design has been released for production, and generally tends to measure the manufacturing process rather than the product, under the assumption that the released product design is final and good. However, this is not necessarily the case, as postrelease design changes or feature additions are not uncommon. It is still possible to obtain useful reliability information from manufacturing testing without diluting any of the process-oriented information that these tests are designed to produce.

6. Functionality testing (see Use of Decision Support Techniques for Information System Risk Management; Stress Screening)

This type of testing usually falls under the category of operation verification. In these tests, a large proportion, if not all, of the products coming off the assembly line are put to a very short test in order to verify that they are functioning properly. In some situations, they may be run for a predetermined "burn-in" time in order to weed out those units that would have early infantile failures in the field.

7. Burn-in testing (see Burn-in Testing: Its Quantification and Applications)

It is intended to minimize, if not eliminate, defective substandard components from going into the next level of assembly [4]. A combination of high temperature, temperature cycling, and nonthermal stresses such as voltage, wattage, mechanical loads, or stresses, etc., is applied to such units as they come

out of production. Failure analysis needs to be conducted to identify the causes of defects creeping into the production of these components [5].

8. Extended postproduction testing (*see Natural Resource Management*)

This type of testing usually gets implemented toward the end or shortly after the product design is released to production. It is useful to structure these types of tests to be identical to the final reliability verification tests conducted at the end of the design phase. The purpose of these tests is to assess the effects of the production process on the reliability of the product. By replicating these tests with actual production units, potential problems in the manufacturing process can be identified before many units are shipped.

9. Design/process change verification testing (*see Expert Judgment*)

This type of testing is similar to the extended postproduction testing in that it should closely emulate the reliability verification testing that takes place at the end of the design phase. This type of testing should occur at regular intervals during production or immediately following a postrelease design change or a change in the manufacturing process. These changes can have a potentially large effect on the reliability of the product and these tests should be adequate, in terms of duration and sample size, to detect such changes.

Reliability Test Procedures

Reliability tests may cost a lot in terms of test facilities, test fixtures, hardware to be tested, and the number of test engineers and technical personnel, as these resources should be available when needed. There are many different reliability tests for different products. Generic procedures of reliability tests are listed below:

1. Determine test requirements and objectives including detailed description of component or equipment to be tested and necessary test equipment and environment. Review existing data from previous tests and other sources to determine if any test requirements can be met without tests. Review a preliminary list of planned tests to determine whether economies can be realized by combining individual test requirements.

2. Prepare the test plan, including test goals, test types, test methods, test environment, test equipment, test period, number of test samples, test cost estimation, how to collect, record, and analyze the test data, and failure description. The test plan must be discussed and approved both by design engineers and reliability engineers.
3. The choice of the test sample size to be used is a very critical item in testing any product. Unfortunately, usually not enough units of a new product or of a remodeled one are tested. A major effort needs to be expended to obtain the right number of test units. Chapter 13 in [6, pp. 699–777] has been put together to address this subject in detail. Example 3 provides cases for the quantification of test sample sizes.
4. Build the test platform including power supply, test chamber, data recording equipment, test data input, and the devices under test.
5. Start the test, record data such as the time and the phenomena of each failure, and replace the failed units if needed.
6. End the test depending on whether the test is time terminated or failure terminated.
7. Process and analyze the collected data, and decide the best fitted distribution of the data and its parameters. Get the basic reliability information such as MTBFs, failure rate, and reliability. Calculate the reliability of the products for certain operation time and decide whether it fulfills the designed-in reliability goal.
8. Do failure modes effects and criticality analysis (FAMECA), which is a step-by-step procedure for the systematic evaluation of the severity of potential failure modes in a system [6]. It helps to identify potential failure modes for a product or process, assess the risk associated with those failure modes, rank the issues in terms of importance, and identify and carry out corrective actions to address the most serious concerns.
9. Formulate the final reliability test report including failure data analysis, reliability quantification, FAMECA results, and conclusions and recommendations to improve the product's design.

Numerical Examples

Example 1 A company has designed a new type of an engine, and now there are 20 units available for

testing to determine the MTBF and the failure rate of these engines. Design the reliability test and do the data analysis based on the test results. Assume that the times to failure of these engines follow the exponential distribution from previous reliability tests on 10 prototypes. The average life of the 10 prototypes is 500 h.

Solution to Example 1

Step 1. Select the reliability test type for this product. Since the life of these engines could be significantly longer than 500 h, and the test cost will be high if all of the 20 units are tested to failure, it is a better choice to apply a time-terminated, nonreplacement test for these 20 engines.

Step 2. Select the test time. The average life of the 10 prototypes is about 500 h; however, the new design will make the engine life longer. So here we choose 900 h for the test time.

Step 3. Build the test platform and environment. Put the 20 engines into working status at the same time.

Step 4. Test them for 900 h. Record the time to failure of each unit that failed during the test. During the test, five failures occur at the times shown in Table 1.

Step 5. Data analysis. According to [7], the equation to estimate the MTBF for the time-terminated nonreplacement test is

$$MTBF = \frac{\sum_{i=1}^r T_i + (N - r)t_d}{r} \quad (1)$$

where N = total number of units under test, r = number of failures in the test, T_i = time to failure of the i th failed unit, and t_d = chosen test duration.

Table 1 Times to failure for Example 1

i , failure number	T_i , time to failure (h)
1	380
2	418
3	543
4	631
5	852

In the example, $N = 20$, $r = 5$, $t_d = 900$, and the T_i are listed in Table 1. Put these values into equation (1) and get

$$\begin{aligned} MTBF &= \frac{(380 + 418 + 543 + 631 + 852) + (20 - 5) \times 900}{5} \\ &= \frac{1487 + 13500}{5} \\ &= \frac{14987}{5} \\ &= 2997.4 \text{ h} \end{aligned}$$

Since we assume that the times to failure of these engines follow the exponential distribution, the failure rate, λ , is obtained from

$$\lambda = \frac{1}{MTBF} = \frac{1}{2997.4} = 0.000335 \text{ fr/h} \quad (2)$$

From these results we see that the new design has a much higher MTBF than the prototypes.

Example 2 In an accelerated life test of 10 electronic chips, the failure data in Table 2, in hours, were obtained [8]:

The accelerated life test was conducted at 150 °C. The expected use operating temperature is 85 °C. The following steps are performed:

1. Use the Arrhenius model and determine the minimum life at the use temperature.
2. Use the Arrhenius model and determine the mean life at the use temperature.

Solutions to Example 2

1. From the test data, the minimum life at the accelerated temperature is

$$L_{T_A^*} = 2750 \text{ h} \quad (3)$$

The accelerated and use temperatures in Kelvin are

$$T_A^* = 150 + 273 = 423 \text{ K} \quad (4)$$

Table 2 The times to failure of 10 electronic chips of Example 2

2750	3100	3400	3800	4100
4400	4700	5100	5700	6400

and

$$T_U^* = 85 + 273 = 358 \text{ K} \quad (5)$$

respectively.

Assuming the activation energy, $E_A = 0.2 \text{ eV}$, for these units, and Boltzmann's constant $= 8.623 \times 10^{-5} \text{ eVK}^{-1}$. Substituting all of the required quantities into the Arrhenius model, we have

$$\begin{aligned} L_{T_{U-\min}^*} &= L_{T_{A-\min}^*} e^{\frac{E_A}{K} \left(\frac{1}{T_U^*} - \frac{1}{T_A^*} \right)} \\ &= (2750) e^{\frac{0.2}{8.623 \times 10^{-5}} \left(\frac{1}{358} - \frac{1}{423} \right)} \end{aligned}$$

or

$$L_{T_{U-\min}^*} = 7442.06 \text{ h} \quad (6)$$

2. From the test data, the mean life, $L_{T_{A-\min}^*}^*$, at the accelerated temperature is

$$\begin{aligned} L_{T_{A-\min}^*}^* &= (2750 + 3100 + 3400 + 3800 \\ &\quad + 4100 + 4400 + 4700 + 5100 \\ &\quad + 5700 + 6400)/10 \end{aligned}$$

or

$$L_{T_{A-\min}^*}^* = 4345 \text{ h} \quad (7)$$

Using the same $E_A = 0.2 \text{ eV}$ as before, and substituting all of the required quantities into the Arrhenius model, yields the mean life at the use temperature of 85°C , or

$$\begin{aligned} L_{T_{U-\min}^*}^* &= L_{T_{A-\min}^*}^* e^{\frac{E_A}{K} \left(\frac{1}{T_U^*} - \frac{1}{T_A^*} \right)} \\ &= (4345) e^{\frac{0.2}{8.623 \times 10^{-5}} \left(\frac{1}{358} - \frac{1}{423} \right)} \end{aligned}$$

or

$$L_{T_{U-\min}^*}^* = 11\,758.45 \text{ h} \quad (8)$$

Example 3 Let us find the sample sizes required to estimate the achievable MTBF of a product at a desired confidence level, or assurance level, so that the desired MTBF will be attained. Let us choose a confidence level of 90% with the following precisions, or errors:

- (a) $\tau = \pm 10\%$, (b) $\tau = \pm 30\%$, and (c) $\tau = \pm 50\%$

Solutions to Example 3

Here the confidence level (CL) is 90%, or $CL = 1 - \alpha = 0.90$, where α is the risk level or the probability that we will not achieve the 90% assurance that the desired MTBF has been achieved. Then, for a precision of $\alpha = 0.10$, $\alpha/2 = 0.05$, we proceed as follows:

First choose $\tau = \pm 10\%$

Quantify

$$\frac{1 + \tau}{1 - \tau} = \frac{1 + 0.10}{1 - 0.10} = \frac{1.10}{0.90} = 1.2222 \quad (9)$$

and substitute into [9]

$$N = \frac{1}{4} + \left(\frac{1}{2} \right) z_{\alpha/2}^2 \left[\frac{1}{\tau} \left(\frac{1}{\tau} + \sqrt{\frac{1}{\tau^2} - 1} \right) - \frac{1}{2} \right]$$

or

$$\begin{aligned} N &= \frac{1}{4} + \left(\frac{1}{2} \right) (1.645)^2 \\ &\quad \times \left[\frac{1}{0.10} \left(\frac{1}{0.10} + \sqrt{\frac{1}{0.10^2} - 1} \right) - \frac{1}{2} \right] \\ &= 270 \end{aligned} \quad (10)$$

which yields a test sample size of $N = 270$ identical products, which is unbelievably large.

The value of 1.645 is obtained from the area tables of the standardized normal distribution by entering them with the value of $\alpha/2 = 0.05$.

Similarly, for a precision of $\pm 30\%$, or $\tau = 0.30$, the same equation yields a sample size of 29 identical products, and for a precision of $\pm 50\%$, or $\tau = 0.50$, the same equation yields a sample size of 10. It can be seen that the sample sizes that should be used should be much larger than those used today in our industries.

Detection Limits

Detection limits (DLs) are established within a chemical laboratory to designate low-level data that cannot be distinguished from a zero concentration (*see Low-Dose Extrapolation*). Higher limits also are used to denote data with low, nonzero concentrations that are too imprecise to report as distinct numbers [1]. Data below both types of limits are reported to the customer as a “nondetect”, such as a value somewhere below 10 (<10). The measurement for the <10 could have been anywhere between 0 to just below 10. The true concentration could have been anywhere between 0 to a small distance above 10. The statistical term for data which include nondetects is “censored data”.

This entry discusses the following:

1. definitions and uses of DLs;
2. methods for using nondetect data in exposure assessments.

Definitions and Uses of Detection Limits

Several types of *reporting limits* are established in a chemical laboratory, one of which is a *detection limit*. Two conventions for calculating and naming reporting limits dominate current practice. The convention followed by many analytical laboratories in the United States uses methods and terminology developed at the US Environmental Protection Agency [1]. Limits are calculated by assuming the measurement variance remains constant from low concentrations down to a level of zero concentration. The DL is set as a multiple of several standard deviations, usually three, above zero. Measurements below the DL are considered not significantly different from zero, and reported as a nondetect. Quantitation limits (QLs) are higher reporting limits representing the level at which individual values may first be reliably quantified. Measurements above the QL are reported as individual values. Practices differ on how to report measurements between the two limits. Here, the chemist generally believes that the analyte is present in the sample, but at concentrations that cannot be quantified with full precision.

When either the DL or the QL is consistently used as the reporting limit, no bias occurs. When all

measurements below the QL (including those below the DL) are reported as <QL, no bias occurs. Or, if the DL is consistently used as the reporting limit so that measurements below the DL are reported as <DL, while measurements between the limits are reported as individual values, no bias occurs. Often the individual values are qualified with a “remark” [2, 3], to indicate that the value is estimated. However, when the two types of reporting limits are mixed, an upward bias called *insider censoring* [4] results. This occurs when data measured below the DL are reported as <QL (QL is the reporting limit for lower measurements), while values between the two limits are given individual values (DL is the reporting limit for higher measurements). Effects of this bias, which may be small but are totally avoidable, are outlined in [4].

The second convention for computing and naming reporting limits is based on terms presented by Currie [5] for radiochemical data (*see Radioactive Chemicals/Radioactive Compounds*), and later applied to water and air measurements. The limit above which observations are considered nonzero is called the *critical level* or *decision limit* rather than DL. A second, higher limit that avoids false nondetections as well as false detections is labeled the *DL*. The concept of a QL is similar in both conventions. In this second convention, the measurement variance is not considered constant between zero and the concentration standards [6], and weighted least squares is used to calculate the location of the DL.

As a third alternative, some scientists advocate the numerical reporting of all readings, including those below detection and QL. However, a measure of analytical error, i.e., 0.3 ± 0.78 , must also be included [7, 8]. If the error is ignored, imprecise measurements are given too much credibility. Values of 0.3 are considered higher than 0.2, for example, when they cannot in reality be distinguished. Specialized procedures such as weighting each measurement by the reciprocal of its variance, so that less precise measurements receive lower weight, must be employed to interpret data reported in this way. Rocke and Lorenzato [9] present one method for estimating the variance of low-level analytical measurements, so that the errors of each measurement can be reported and used in subsequent computations.

Methods for Using Nondetect Data in Exposure Assessments

Methods for censored data have been developed and used for decades in the fields of reliability analysis [10] (see **Reliability Data; Systems Reliability**) and survival analysis [11]. However, many risk analysts are not familiar with these methods, and often substitute (fabricate) values for nondetects. Substitution replaces nondetects with an artificial value not measured in the laboratory. For assessments of water chemistry, 1/2 of the DL is typically substituted, while in air chemistry assessments $1/\sqrt{2}$ times the DL is most often used [12]. Substitution produces biased estimates of mean and percentiles, and generally underestimates dispersion measures such as the standard deviation. In numerous simulation studies, substitution performed very poorly [13–15]. In addition, two sources of substitution error are not evaluated in simulations – changing DLs in response to changing laboratory protocols and to characteristics of the media being measured [16]. To illustrate the latter, interferences from other chemicals may increase the DL of the chemical of interest for some observations, but not others. Substituted values then increase for some, though true concentrations do not.

Substitution is best avoided, except for the (perhaps common) substitution of zero and DL to estimate the highest and lowest possible values for the mean. Note that extremes for other statistics, however, such as the standard deviation and *t*-tests cannot be obtained in this way [17].

There are three alternative methods to substitution:

1. Distributional methods

These methods assume that the shape of the data distribution can be modeled by a lognormal, gamma, or other standard distribution. For censored data, statistics (a mean, or regression slope) are computed using maximum likelihood estimation or MLE [12], rather than with the traditional formulae (arithmetic average, least squares, etc.).

2. Nonparametric methods

These methods do not assume a specific distributional shape, but instead use the observed percentiles of the measured data. Kaplan–Meier methods [12] form the basis for most nonparametric censored procedures.

3. Binomial methods

These methods classify data into two categories, below and above a DL. The proportion of values

above the limit are then interpreted, rather than means or medians.

These methods are applied to familiar tasks of chemical risk assessment:

Computing the Mean and Its Confidence Intervals (UCL95)

Exposure concentrations are often estimated by the mean of samples over time or space. Concentration data are most often skewed, in part because they cannot be negative. Estimating the mean for skewed data is difficult to do well. Lognormal distributions are one solution. The logarithms of data are assumed to follow a normal distribution, allowing the original values to be skewed. Frome and Wambach [18] recommend using lognormal maximum likelihood for estimating the mean, as long as data are not highly skewed. Skewness makes estimates of the standard deviation of logarithms unstable, and the standard deviation of logarithms affects estimates of both mean and standard deviation of the original units. When data are highly skewed, the nonparametric Kaplan–Meier method was recommended instead [18].

The UCL95 is a value with only a 5% chance of being less than the true population mean. It is used in probabilistic and deterministic risk assessments as an upper limit of where the population mean is located. Cox's method can estimate the UCL95 of a lognormal distribution [18]. Singh *et al.* [15] performed an exhaustive study of parametric and nonparametric methods for estimating the UCL95 for data with nondetects. Earlier guidance documents recommended substitution of one-half the DL with fewer than 15% nondetects [19]. In contrast, Singh *et al.* [15] found that substitution provides poor coverage (percent of time the statistic equaled or exceeded the population mean) for any distribution, sample size, or percent of censoring. The nonparametric Kaplan–Meier method provided better coverage than MLE, and far better than substitution methods. To compute the UCL95 from the Kaplan–Meier mean, bootstrapping or the familiar *t*-interval formula are used, depending on data characteristics [15].

Computing Percentiles

High percentiles such as the 90th or 95th percentiles of measured concentrations are often used to

estimate the reasonable maximum exposure (RME). Percentiles are computed using measured data alone (nonparametric method) for large data sets, or along with an assumed distribution (parametric method) for more moderate sample sizes. If a single DL is used, and is low in comparison to most of the data, nondetect data will not alter nonparametric estimates of high percentile values – neither substitution nor the other, better methods are necessary. For 35% nondetects below a single DL, for example, any percentile higher than the 35th percentile will be a detected value. In contrast, parametric estimates use every observation to estimate mean and standard deviation as steps to estimating high percentiles. Parametric methods that incorporate nondetects properly (MLE) produce far better estimates than do substitution or deletion of nondetects. For data with multiple DLs, all percentiles below the highest limit are affected by nondetects. Methods such as in reference [12] or [10] should be used.

Correlations

The likelihood r and Kendall's tau correlation coefficients [12] measure the strength of associations between variables for data with one or more DLs. Likelihood r is a parametric coefficient analogous to Pearson's r , but applicable to censored data. Kendall's tau is a nonparametric correlation coefficient commonly used in trend analysis. With both coefficients, nondetects are represented as "below the DL" without requiring a substituted value.

Tau is computed by determining whether y varies randomly or in concert with changes in x [12]. For example, changes in y from <1 to 3 are increases, as are changes from <3 to 10, so that single and multiple DLs can be incorporated by tau. Comparisons between <1 and <3 , or between <3 and 2, are considered ties because the direction of change cannot be determined.

Both of these correlation coefficients vastly outperform Pearson's r , which, in order to be computed, requires a substituted value for nondetects (surely to be incorrect, as is therefore the coefficient) [17]. Tau is invariant to monotonic transformations, while likelihood r is not.

Regression with Covariates

Regression models are used to either estimate a y variable from one or more covariates, or to better

understand the magnitude of the effect of a covariate as expressed by its slope coefficient. Maximum likelihood regression (also called *failure-time regression*) can be computed for data with one or more DLs, with assumptions and tests for significance similar to ordinary regression [12]. Likelihood ratio tests determine whether individual covariates should be included in the regression model. The likelihood r -squared reports a measure of the quality of the regression [11]. One limitation of MLE regression is that no censoring is allowed in the x variables, but only in the y variable [12].

Nonparametric regression is also available when there is only one x variable. The procedure is based on Kendall's tau [20]. Called *ATS* or the *Akritas-Theil-Sen* method by Helsel [12], it allows censoring in both the x and y variables. The ATS slope is like a median line through the data – outliers do not have as strong an influence on the position of this line as they do with parametric regression.

Rather than predicting concentrations, logistic regression can be used to predict the probability of a binary outcome, such as above or below the DL, or above or below the RME. The probability of detecting a pesticide, for example, can be related to one or more x variables describing the intensity of its use, its transport in the environment, etc. The likelihood r -squared again measures the quality of the regression model, while likelihood ratio tests determine which covariates best predict the probability of exceeding the limit/RME. Logistic regression (*see Logistic Regression*) is most applicable when there is a high proportion of nondetects.

Availability of Software

Commercial statistics software generally includes methods for censored data, as well as logistic regression. Nonparametric procedures currently expect censored data to be "greater than" values rather than nondetects, so data with nondetects must be transformed prior to using the nonparametric routines [12]. Maximum likelihood methods can incorporate nondetects without any modification.

The R statistical software system is freely available for Windows, Macintosh and Linux operating systems at the comprehensive R archive network (CRAN, <http://www.r-project.org>). A contributed package named *NADA for R* is available there which

implements the methods for censored data found in Helsel [12].

Macros for Minitab statistical software to implement methods for nondetect data are available at <http://www.practicalstats.com/nada>. ATS regression methods, nonparametric and parametric hypothesis testing procedures, and computing descriptive statistics are among those listed.

SPLIDA for S-Plus implements routines for reliability analysis discussed in reference [10] for S-Plus statistical software. These routines expect censored values to be “greater than” values, and therefore do not explicitly incorporate nondetects. But the methods could easily be adapted by first employing the “flipping” transformation [12].

Digital Governance, Hotspot Detection, and Homeland Security

In geospatial and spatiotemporal surveillance, it is important to determine whether any variation observed may reasonably be due to chance or not. This can be done using tests for spatial randomness, adjusting for the uneven geographical population density as well as for age and other known risk factors. One such test is the spatial scan statistic (see **Syndromic Surveillance**), which is used for the detection and evaluation of local clusters or hotspot areas. This method is now in common use by various governmental health agencies, including the National Institutes of Health, the Centers for Disease Control and Prevention, and the state health departments in New York, Connecticut, Texas, Washington, Maryland, California, and New Jersey. Other test statistics are more global in nature, evaluating whether there is clustering in general throughout the map, without pinpointing the specific location of high or low incidence or mortality areas.

The declared purpose of digital governance is to empower the public with information access, analysis, and policy to enable transparency, accuracy, and efficiency for societal good at large. Hotspot detection and prioritization become natural undertakings as a result of information access over space and time. Hotspot means spot that is hot, which is of special interest or concern (see **Hazardous Waste Site(s)**). Geoinformatic surveillance for spatial and temporal hotspot detection and prioritization is crucial in the twenty-first century, so also the need for geoinformatic surveillance decision support system equipped with the next generation of geographic and networked hotspot detection, prioritization, and early warning with emerging hotspots.

Scan Statistic Methodology and Technology

Two main problems arise in geographical surveillance for a spatially distributed response variable. These are (a) identification of areas having exceptionally high (or low) response and (b) determination of

whether the elevated response can be attributed to chance variation (false alarm) or is statistically significant. The spatial scan statistic [1] has become a popular method for detection and evaluation of disease clusters. In space–time, the scan statistic can provide early warning of disease outbreaks and can monitor their spatial spread.

Spatial Scan Statistic Background

The spatial scan statistic deals with the following situation. A region R of Euclidian space is tessellated or subdivided into cells labeled by the symbol a . Data is available in the form of a count Y_a (non-negative integer) on each cell a . In addition, a “size” value A_a is associated with each cell a . The cell sizes A_a are regarded as known and fixed, while the cell counts, Y_a , are random variables. In the disease setting, the response Y_a is the number of diseased individuals within the cell and the size A_a is the total number of individuals in the cell. Generally, however, the size variable is adjusted for factors such as age, gender, environmental exposures, etc., that might affect incidence of the disease. The disease rate within the cell is Y_a/A_a . The spatial scan statistic seeks to identify “hotspots” or clusters of cells that have an elevated rate compared with the rest of the region, and to evaluate the statistical significance (p value) of each identified hotspot. These goals are accomplished by setting up a formal hypothesis-testing model for a hotspot. The null hypothesis asserts that there is no hotspot, i.e., that all cells have (statistically) the same rate. The alternative for null hypothesis states that there is a cluster Z such that the rate for cells in Z is higher than for cells outside Z . An essential point is that the cluster Z is an unknown parameter that has to be estimated. Likelihood methods are employed for both estimation and significance testing. Candidate clusters for Z are referred to as zones. Ideally, maximization of the likelihood should search across all possible zones, but their number is generally too large for practical implementation. Various devices (e.g., expanding circles) are employed to reduce the list of candidate zones to manageable proportions (see Figure 1). Significance testing for the spatial scan statistic employs the likelihood ratio test; however, the standard χ -square distribution cannot be used as reference or null distribution – in part because the zonal parameter Z is discrete. Accordingly, Monte

Figure 1 A small sample of the circles used

Carlo simulation is used to determine the needed null distributions.

Explication of a likelihood function requires a distributional model (response distribution) for the response Y_a in cell a . This distribution can vary from cell to cell but in a manner that is regulated by the size variable A_a . Thus, A_a enters into the parametric structure of the response distribution. In disease surveillance, response distributions are generally taken as either binomial or Poisson, leading to comparatively simple likelihood functions.

Limitations of Current Scan Statistic Methodology

Available scan statistic software suffers from several limitations (see Figure 2). First, circles have been used for the scanning window, resulting in low

power for detection of irregularly shaped clusters. Secondly, the response variable has been defined on the cells of a tessellated geographic region, preventing application to responses defined on a network (stream network, water distribution system, highway system, etc.). Thirdly, response distributions have been taken as discrete (specifically, binomial or Poisson). Finally, the traditional scan statistic returns only a point estimate for the hotspot and does not attempt to assess estimation uncertainty. All of these limitations are addressed by the innovation proposed next.

The Proposed Approach

In the approach to the scan statistic, the geometric structure that carries the numerical information is an abstract graph consisting of (a) a finite collection of vertices and (b) a finite set of edges that join certain pairs of distinct vertices. A tessellation determines such a graph: vertices are the cells of the tessellation and a pair of vertices is joined by an edge whenever the corresponding cells are adjacent. A network determines such a graph directly. Each vertex in the graph carries three items of information: (a) a size variable that is treated as known and nonrandom, (b) a response variable whose value is regarded as a realization of some probability distribution, and (c) the probability distribution itself, which is called the response distribution. Parameters of the response distribution may vary from vertex to vertex, but the mean response (i.e., expected value of the response distribution) should be proportional to the value of the size variable for that vertex. The response rate is

(a)

- Cholera outbreak along a river flood-plain
- Small circles miss much of the outbreak
 - Large circles include many unwanted cells

(b)

- Outbreak expanding in time
- Small cylinders miss much of the outbreak
 - Large cylinders include many unwanted cells

Figure 2 Scan statistic zonation for circles (a) and space–time cylinders (b)

the ratio response/size and a hotspot is a collection of vertices for which the overall response rate is unusually large.

ULS Scan Statistic

A new version of the spatial scan statistic is designed for detection of hotspots of arbitrary shapes and for data defined either on a tessellation or a network. This version looks for hotspots from among all connected components of upper level sets of the response rate and is therefore called the ULS scan statistic [2, 3]. The method is adaptive with respect to hotspot shape, since candidate hotspots have their shapes determined by the data rather than by some *a priori* prescription like circles or ellipses. This data dependence will be taken into account in the Monte Carlo simulations (see **Enterprise Risk Management (ERM); Pesticide Risk; Systems Reliability**) used to determine null distributions for hypothesis testing. It will also compare performance of the ULS scanning tool with that of the traditional spatial scan statistic. The key element here is enumeration of a searchable list of candidate zones Z . A zone is, first of all, a collection of vertices from the abstract graph; secondly, those vertices should be connected because a geographically scattered collection of vertices would not be a reasonable candidate for a “hotspot.” Even with this connectedness limitation, the number of candidate zones is too large for a maximum likelihood search in all but the smallest of graphs. The list of zones is reduced to a searchable size in the following way. The response rate at vertex a is $G_a = Y_a/A_a$. These rates determine a function $a \rightarrow G_a$ defined over the vertices in the graph. This function has only finitely many values (called levels) and each level, g , determines an upper level set U_g defined by $\{a : G_a < g\}$. Upper level sets do not have to be connected but each upper level set can be decomposed into the disjoint union of connected components. The list of candidate zones Z for the ULS scan statistic consists of all connected components of all upper level sets. This list of candidate zones is denoted by Ω_{ULS} . The zones in Ω_{ULS} are certainly plausible as potential hotspots, since they are portions of upper level sets. Their number is small enough for practical maximum likelihood search – in fact, the size of Ω_{ULS} does not exceed the number of vertices in the abstract graph (e.g., the number of cells in the tessellation). Finally, Ω_{ULS} becomes a tree under set inclusion, thus facilitating

Figure 3 ULS connectivity tree

computer representation. This tree is called the *ULS tree*; its nodes are the zones $Z \in \Omega_{\text{ULS}}$ and are therefore collections of vertices from the abstract graph. Leaf nodes are (typically) singleton vertices at which the response rate is a local maximum; the root node consists of all vertices in the abstract graph (see Figure 3).

Typology of Space–Time Hotspots

Scan statistic methods extend readily to the detection of hotspots in space–time. The space–time version of the circle-based scan employs cylindrical extensions of spatial circles and cannot detect the temporal evolution of a hotspot. The space–time generalization of the ULS scan detects arbitrarily shaped hotspots in space–time. This helps classify space–time hotspots into various evolutionary types – a few of which appear on the left-hand side of Figure 4. The merging hotspot is particularly interesting because, while it comprises a connected zone in space–time, several of its time slices are spatially disconnected.

Key Applications

Broadly speaking, the proposed geosurveillance project and its forum identify several case studies around the world. This section provides a selection of illustrative applications and case studies.

Figure 4 The four diagrams on the left depict different types of space–time hotspots. The spatial dimension is shown schematically on the horizontal axis and time on the vertical axis. The diagrams on the right show the trajectory (sequence of time slices) of a merging hotspot

Figure 5 The ocean sampling network

Tasking of a Self-Organizing Oceanic Surveillance Mobile Sensor Network

The autonomous ocean sampling network (AOSN) simulator is used to study coordination and control strategies for high-resolution, spatiotemporally coordinated surveys of oceanographic fields such as bathymetry, temperature, and currents using autonomous, unmanned, undersea vehicles Figure 5. Currently, the network of mobile sensor platforms is autonomous and self-organizing once given high-level tasking from an external tactical coordinator. This case study proposes to use ULS scan statistic theory to identify hotspots in data gathered by the sensor network and use this information to dynamically task mobile sensor platforms so that more data can be gathered in the areas of interest. By detecting

hotspots and tasking accordingly, network resources are not wasted on mapping areas of little change. The ability of the sensor network to dynamically task its own components expands the network’s mission and increases the reactivity to changing conditions in a highly dynamic environment [4–6].

Early Detection of Biological Invasions

Intentional and unintentional introductions of nonnative exotic species have major economic and ecological impacts across the United States. A National Academy of Sciences report [7] estimates the cost of lost crops and containment measures at \$137 billion per year. Early detection of invasive weedy plants is the only cost-effective and tractable option for their containment or eradication. But systems for synthesizing on-the-ground observation, spatial data, and newly acquired remotely sensed data are lacking. We will apply the ULS scan statistic and prioritization tools to obtain more efficient surveys for invasive species and to improve the responsiveness of environmental managers to outbreaks. Japanese stiltgrass has become established in forests and waterways in the eastern United States and threatens to significantly reduce forest and riparian species diversity, and impede water flow in rivers and streams. Often locally established populations have begun to spread before those populations have been detected and likelihood for successful management is severely compromised. Coupling the data resources with the

Figure 6 Biological invasion

scan statistic represents a promising approach to preventing the transition of invasive plants from isolated established populations to spreading ones, like that depicted in Figure 6 [8, 9].

Development of Remote Sensing Methods for Crop Bioterrorism

Testimony to the House National Security Subcommittee this past fall stressed the high probability that

crop terrorism could and would occur. The logistics of ground-based monitoring are daunting, and point to a strong need to monitor US cropland by remote sensing. Remote sensing, to be timely and effective, should resolve zones of infection as small as 5 m in diameter. Improvements in the next generation of sensors will have to be made, as will the techniques for handling the huge volumes of high-resolution data. Another difficulty has been the development of high-quality signatures detectable from airborne or space-borne platforms. To date, reliable detectable signatures have been difficult to obtain. We propose to defeat this impasse by integrating biologists, engineers, and statisticians to generate high-quality hyperspectral signatures, to determine signal strength on unique portions of these signatures, and to develop goals for instrument resolution from various platforms. Specific goals are as follows: (a) develop signatures for two key pathogens using ground-based, portable hyperspectral cameras; (b) determine signal strength *versus* noise of plants infected with single or multiple pathogens and/or insects; (c) enhance hardware and processing algorithms to filter and resolve crop pathogen signals; (d) provide goals for the next generation of air- and space-borne sensors for high-threat pathogens. Figure 7 depicts the process from signature development through identification of threat areas, signal acquisition/processing to the development of an anomaly report [10, 11].

Figure 7 Crop attack decision support system

Cyber Security and Computer Network Diagnostics

Securing the nation's computer networks from cyber attacks is an important aspect of national Homeland Security. Network diagnostic tools aim at detecting security attacks on computer networks. Besides cyber security, these tools can also be used to diagnose other anomalies such as infrastructure failures and operational aberrations. Hotspot detection forms an important and integral part of these diagnostic tools for discovering correlated anomalies. It is constructive to develop a network diagnostic tool at a functional level. The goal of network-state models is to obtain the temporal characteristics of network elements such as routers, typically in terms of their physical connectivity, resource availability, occupancy distribution, blocking probability, etc. There is some prior work [12] in developing network-state models for connectivity and resource availability. Models have also been developed for studying the equilibrium behavior of multidimensional loss systems. The probabilistic finite-state automaton (PFSA) describing a network element can be obtained from the output of these state models. A time-dependent crisis index is determined for each network element, which measures their normal behavior pattern compared to crisis behavior. The crisis index is the numerical distance between the stochastic languages generated by the normal and crisis automata. Use of the variational distance between probability measures seems attractive, although other distances can also be considered. The crisis behavior can be obtained from past experience. The crisis indices over a collection of network elements are then used for hotspot detection using scan statistic methodology. These hotspots help to detect coordinated security attacks geographically spread over a network.

Drinking Water Quality and Water Utility Vulnerability

New York City has installed 892 drinking water sampling stations across the five boroughs. Each 4.5-ft high station is located outdoors and draws water from a nearby water main (Figure 8). The purpose is to monitor general water quality, detect potential health threats, and thwart bioterror activity. Sampling frequency was increased after the 9/11 attacks and, currently, about 47 000 water samples are analyzed

Figure 8 Drinking water sampling station

annually. Parameters analyzed include bacteria, chlorine, pH, inorganic and organic pollutants, color, turbidity, odor, and many others. The network version of the ULS scan statistic can provide a real-time surveillance system for detecting and evaluating water quality hotspots within the distribution system on a parameter-by-parameter basis.

An overall assessment of water quality at each sampling station taking all parameters into account is achieved by employing recent progress in multi-criterion ranking using partially ordered set (poset) prioritization [13].

Syndromic Surveillance Network and Early Warning

Emerging hotspots for disease, biological agents, or medical effects of pollution are identified through modeling events at local hospitals. A time-dependent crisis index is determined for each hospital in a network spread over a city, state or the whole country. This index measures the behavior patterns at each hospital compared to crisis behavior. The behaviors are based on series of hospital admission records containing symptoms and diagnoses. The basic components of behaviors are events, which in this case are hospital admissions. The important attributes of admissions are the information on the admission records and how frequently admissions are

Figure 9 The overall procedure

occurring compared to normal, noncrisis behavior. The behavior stream is represented as PSFA and by the corresponding formal stochastic language. The method of epsilon machines [14, 15] is used to estimate the automaton from the current behavior stream. The variational distance between stochastic languages provides a quantitative measure of how close the current behavior is to that of a crisis. This distance is called the crisis index. The crisis index over the network of hospitals is used for hotspot detection by the ULS scan statistic (see Figure 9).

West Nile Virus: An Illustration of the Early Warning Capability of the Scan Statistic

Since the 1999 West Nile (WN) virus outbreak in New York City, health officials have been searching for an early warning system that could signal increased risk of human WN infection, and provide a basis for targeted public education and increased mosquito control. Birds and mosquitoes with laboratory evidence of WN virus preceded most human infections in 2000, but sample collection and laboratory testing are time consuming and costly. The

cylinder-based space–time scan statistic for detecting small area clustering of dead bird reports has been assessed for its utility in providing an early warning of WN virus activity (Figure 10) [16].

All unique nonpigeon dead bird reports were categorized as “cases” if occurring in the prior 7 days and “controls” if occurring during a historic baseline. The most likely cluster area was determined using the scan statistic and its statistical significance was evaluated using Monte Carlo hypothesis testing. Analyses were performed in a prospective simulation for 2000 and in real time during 2001.

For the 2000 data, dead bird clustering was found in Staten Island over 4 weeks prior to laboratory evidence of WN virus in birds and mosquitoes from this area. Real-time implementation in 2001 led to intensified larval control in eastern Queens, over 3 weeks prior to laboratory confirmation from this cluster area. Dead bird clusters were identified around the residence of five of seven human infections, 0–40 days (median 12) prior to the onset of illness and 12–45 days (median 17) prior to human diagnosis.

Figure 10 Event map

It has been concluded that scan statistical cluster analysis of dead bird reports may provide early warning of viral activity among birds and of subsequent human infections. Analysis with the ULS space–time scan statistic will be worthwhile. Since the latter allows for arbitrarily shaped clusters in both the spatial and temporal dimensions, there is potential for earlier detection with a reduced false alarm rate.

New York City Subway System Syndromic Surveillance

For certain problems, there is an underlying network structure on which we want to perform the cluster detection and evaluation. For example, the New York City Health Department is monitoring the New York subway system and water distribution networks for bioterrorism attacks. In such a scenario, a circular scan statistic is not useful as two individuals close to each other in Euclidian distance may be very far from each other along the network. However, the ULS methods will be employed for the detection and evaluation of clusters on a predefined network. The essentially linear structure of these networks, compared to tessellation-derived networks, is expected to have a major impact on the form of the null distributions and their parametric approximations.

The New York City Department of Health (DOH) and Metropolitan Transportation Authority (MTA) began monitoring subway worker absenteeism in October 2001 as one of several surveillance systems for the early detection of disease outbreaks. Each day the MTA transmits an electronic line list of workers absent the previous day, including work location and

reason for absence. DOH epidemiologists currently monitor temporal trends in absences in key syndrome categories (e.g., fever-flu or gastrointestinal illness). Analytic techniques are needed for detecting hotspots within the subway network.

Looking Forward

We now live in the age of geospatial technologies. The age old geographic issues of societal importance are now thinkable and analyzable. The geography of disease is now just as doable as genetics of disease, for example. And it is possible to pursue it in an intelligent manner with the rapidly advancing information technology around.

Government agencies continue to require meaningful summaries of georeferenced data to support policies and decisions involving geographic assessments and resource allocations, so also the public with initiatives of digital governance in the country and around the world.

This article briefly describes a prototype hotspot detection system for hotspot delineation and provides a variety of case studies and illustrative applications of societal importance for homeland security.

Surveillance geoinformatics of hotspot detection and prioritization is a critical need of the twenty-first century. Next generation decision support system within this context is crucial. It will be productive to build on the present effort in the directions of prototype and user-friendly methods, tools, and software, and also in the directions of thematic groups, working groups, and case studies important at various scales and levels. The authors have such a continuation effort in progress within the context of digital governance with National Science Foundation (NSF) support and would welcome interested readers to join in this collaborative initiative.

Dioxin Risk

“Dioxin” refers to a large group of structurally related chemicals called *polychlorinated dibenzo-*p*-dioxins*, although it is sometimes used to refer specifically to one such substance, 2,3,7,8-tetrachloro dibenzo-*p*-dioxin (TCDD). Dioxins comprise two benzene rings connected by two oxygen atoms and contain four to eight chlorine atoms. Dioxins are unintentional byproducts of combustion, both anthropogenic (e.g., municipal waste incineration) and naturally occurring (e.g., forest fires). Dioxins can also form as a result of certain industrial processes, such as bleached paper manufacture. They are persistent in the environment and in the body. They are both ubiquitous and persistent throughout the environment and in all our bodies. Focus on dioxin risks began in the 1940s and 1950s when workers involved in manufacturing 2,4,5-T, the herbicide that was used to make the Vietnam War-era defoliant Agent Orange, developed a serious form of acne. Later studies showed that the workers’ acne and 2,4,5-T’s ability to produce birth defects in rats could be attributed to the presence of dioxin. Many other sources and effects of dioxin have since been identified.

Exposure

The toxicity of different dioxin compounds varies considerably in laboratory animals but generally involves similar biological modes of action. As most human exposure involves complex mixtures of many dioxins, quantitative exposure estimates are referred to in terms of toxic equivalence (TEQ). Toxic equivalency factors (TEFs) for different dioxin compounds have been established by the World Health Organization (WHO) and are calculated relative to TCDD using the results of comparative toxicity studies in laboratory animals [1] (see **Cancer Risk Evaluation from Animal Studies**). So, for example, TCDD is assigned a TEF of 1; hexachlorodibenzo-*p*-dioxins are somewhat less toxic, so they are assigned a TEF of 0.1; and octachlorodibenzo-*p*-dioxin is considerably less toxic, so it is assigned a TEF of 0.0001. Concentrations of different dioxins in a mixture are multiplied by their appropriate TEFs and summed together to estimate a total TEQ for a given exposure situation. Dioxins are stored in body fat and

their half-lives vary considerably, ranging from about 6 months to 20 years [2], so body burdens of dioxins do not tend to reflect exposure quantitatively.

Since risk management aimed at reducing emissions of dioxins was initiated in the 1970s, substantial decreases in environmental levels and in body burdens have been observed. Although somewhat uncertain due to changes in analytical methodologies over time, available data on emissions, environmental and food levels, and tissue levels indicate a several-fold reduction in exposures and body burdens since 1970 [3]. The United States Environmental Protection Agency (USEPA) reported that emissions from quantified sources – such as waste incineration, pesticide manufacture, and chlorine bleaching of pulp and paper – decreased from more than 14 000 g TEQ/year in 1987 to about 1500 g TEQ/year in 2000 – a 90% decrease – and are expected to continue to decline [4]. Human body burdens of TCDD in the United States decreased 10-fold and dioxin TEQ decreased 4- to 5-fold between 1972 and 1999, which, owing to their long elimination half-lives, implies a decrease in exposure of more than 95% [3]. USEPA has estimated that more than 90% of the remaining human exposures to dioxins occur through food consumption, primarily from animal fat [5, 6]. Uncontrolled combustion, including open burning of household trash, agricultural burning, and landfill fires, are now considered to be the largest unaddressed sources of dioxin in the environment [6].

Toxicity

Studies suggest that exposure of the general population to low environmental levels of dioxins does not result in clinical evidence of disease. However, poisoning incidents involving high levels of exposure have produced several effects, especially a persistent, acne-like skin disease called *chloracne*. Studies in workers exposed to dioxins occupationally provide limited evidence of their ability to increase cancer rates. Children exposed accidentally to high levels of dioxins either before or after birth were found to have a number of developmental deficits [7].

There is a large body of literature on the toxicity of dioxins in laboratory animals, although most studies have focused on TCDD. Reviews of that literature are available [5, 8, 9]. Dioxins have been reported to produce effects such as cancer, developmental

toxicity, immunotoxicity, and reproductive toxicity in a variety of species. Developmental effects on the reproductive system are the effects that occur at the lowest doses in many laboratory animals, so those effects have been considered by several organizations to be the most sensitive endpoint of concern for evaluating human risk. The extent to which the laboratory animal data are relevant to humans is controversial, however, in part because human developmental stages do not map well to rodent development [10, 11]. Prenatal exposure of Rhesus monkeys to low doses of TCDD has been reported to induce developmental neurobehavioral effects [12, 13] including cognitive deficits and changes in social interaction. Those effects were considered the most relevant sensitive effect for evaluating human health risk by the US Agency for Toxic Substances and Disease Registry [8].

Safety

Effects of dioxins are generally attributed to their initial interaction at the cellular level with the aryl hydrocarbon hydroxylase (Ah) receptor, which regulates the activity of certain metabolic enzymes. While interaction with the Ah receptor appears to be necessary for most biological effects of dioxins, it is solely insufficient to account for all of those effects. Studies show that the binding affinity of the human Ah receptor resembles that of species that are relatively insensitive to dioxin toxicity, with data suggesting humans are likely to be one to two orders of magnitude less sensitive to the Ah-receptor-related effects of TCDD than rats and monkeys [14].

The fact that laboratory animals are more sensitive than humans and poor surrogates for predicting quantitative risks makes them good models for establishing safe levels of human exposure. Any exposure limit based on a sensitive endpoint in laboratory animals can be expected to be especially protective of human health, including the health of potentially sensitive individuals or life stages. The Joint FAO/WHO Expert Committee on Food Additives has proposed a tolerable monthly intake of 70 pg TEQ/kg body weight as being protective of human health, based on developmental effects observed in male rats exposed to TCDD during gestation [15, 16]. This value translates to a tolerable daily intake (TDI) of 2 pg TEQ/kg body weight. The UK Food Standards

Agency's Committee on Toxicity has recommended a TDI of 2 pg TEQ/kg body weight [17], as has the European Commission's Scientific Committee on Food [18] (although their specific recommendation is 14 pg TEQ/kg body weight/week), consistent with the FAO/WHO TDI. The USEPA has been debating the appropriate exposure limit for dioxins since 1985; no risk estimate or exposure limit is agreed upon. No acceptable daily intake has been established by the US Food and Drug Administration.

Disease Mapping

Background

The analysis of epidemiological or public health data is georeferenced. Typically, the data arises in two forms: either (a) the residential address of cases of disease is known or (b) arbitrary small areas such as census tracts, zip codes, or postcodes have counts of disease observed within them. The locational information is used in the analysis usually to make inferences about spatial health effects (*see Geographic Disease Risk*).

Often hypotheses of interest in disease mapping focus on whether the residential address of cases of disease yields insight into etiology of the disease or, in a public health application, whether adverse *environmental health risks* (*see Environmental Health Risk*) exist locally within a region (as exemplified by local increases in disease risk). For example, in a study of the relationship between malaria and diabetes in Sardinia a strong negative relationship has been found. This relation had a spatial expression and the geographical distribution of malaria was important in generating explanatory models for the relation [1]. In public health practice, it is of considerable importance to be able to assess whether localized areas which have larger than expected numbers of cases, of disease, are related to any underlying environmental cause. Here, spatial evidence of a link between cases and a source is fundamental in the analysis. Evidence such as a decline in risk with distance from the putative source of hazard, or elevation of risk in a preferred direction is important in this regard (*see e.g. [2; 3, chapter 7; 4]*).

There are four main areas where statistical methods have seen development: *disease map reconstruction*, *disease clustering*, *ecological analysis*, and *disease map surveillance*. The term *disease mapping* is used in different contexts to either signify the group of methods that are applied to disease maps, or more specifically to the estimation of relative risk from disease maps (*disease map reconstruction*). Hence, there can be some confusion in the use of this term. It is appropriate to consider some common themes or issues, which arise in all areas of the subject.

Basic Definitions and Models

A fundamental feature of data available for analysis is that it is usually discrete (either in the form of a point process or counting process), and the cases of concern arise from within a local human population, which varies in spatial density and in susceptibility to the disease of interest. Hence, any model or test procedure must make allowance for this background (nuisance) population effect. The background population effect can be allowed for in a variety of ways. For count data it is commonplace to obtain expected rates for the disease of interest based on the age–sex structure of the local population, and some crude estimates of local relative risk are often computed from the ratio of observed to expected counts (e.g., SMRs: standardized mortality/incidence ratios). For case event data, expected rates are not available at the resolution of the case locations and the use of the spatial distribution of a control disease has been advocated. In that case, the spatial variation in the case disease is compared to the spatial variation in the control disease. A major issue in this approach is the correct choice of control disease. It is important to choose a control which is matched to the age–sex structure of the case disease but is unaffected by the feature of interest. For example, in the analysis of cases around a putative health hazard, a control disease should not be affected by the health hazard. Counts of control disease cases could also be used instead of expected rates when analyzing count data. Figures 1 and 2 display case event and control data maps for a region of the United Kingdom for a fixed period. Figure 3 displays a typical count data example. For the case event data in Figures 1 and 2 the object was to examine the spatial distribution of excess risk for gastric and esophageal cancer beyond that found in the control disease. Figure 3 is a map of the crude counts of congenital deaths in South Carolina. The spatial analysis of these deaths could be related to adverse environmental risk differences in the state. A geographical analysis could point to areas of adverse risk that require further investigation.

Case Event Data

Case event locations often represent residential addresses of cases and the cases arise from a heterogeneous population that varies both in spatial density

Figure 1 Distribution of death certificate addresses of gastric and esophageal cancer in Arbroath, Scotland, UK (1966–1976)

Figure 2 Control distribution: distribution of death certificate addresses for lower body cancers in Arbroath, UK (1966–1976)

and in susceptibility to disease. A heterogeneous Poisson process model is often assumed as a starting point for further analysis. The focus of interest for making inference regarding parameters describing excess risk lies in a relative risk function, which is

Figure 3 Distribution of counts of congenital deaths within the counties of South Carolina, USA (1990)

included in the first order intensity of the Poisson process.

It is possible that population or environmental heterogeneity may be unobserved in the data set. This could be because either the population background hazard is not directly available, or the disease displays a tendency to cluster (perhaps owing to unmeasured covariates). The heterogeneity could be spatially correlated, or it could lack correlation in which case it could be regarded as a type of “overdispersion”. One can include such unobserved heterogeneity within the framework of conventional models as a random effect.

Count Data

A considerable literature has developed concerning the analysis of count data in spatial analysis of disease (e.g., see reviews in [3] and [4]).

The usual model adopted for the analysis of region counts assumes that the counts are independent Poisson random variables with parameter θ_i in the i th region. This model may be extended to include unobserved heterogeneity between regions by introducing a prior distribution for the log relative risks ($\log \theta_i$). Incorporation of such heterogeneity has become a common approach and the Besag, York and, Mollié (BYM) model is now a standard model. A full Bayesian analysis using this model is available on WinBUGS. A recent overview of Bayesian methods (see **Bayesian Statistics in Quantitative Risk Assessment**) in disease mapping is found in [5].

Distributions for Loss Modeling

In this article, we focus on models that can be used for the size and number of losses. For sizes of loss, we restrict ourselves to distributions that do not take on negative values. Similarly, when considering the number of losses occurring in a fixed time period, that number cannot be negative.

When searching for a distribution function to use as a model for a random phenomenon, it can be helpful if the field can be narrowed from this infinitely large set to a small set containing distribution functions with a sufficiently large variety of shapes to capture features that are encountered in practice. We provide a (partially) unified approach to distributions by combining them into nested “families”.

Continuous Size-of-Loss Distributions

We examine a number of distributions that can be used for modeling the amount of loss arising from loss events. By definition, losses can only take on values that are nonnegative. Hence we only look at distributions whose random variable can only take on nonnegative values. For most distributions, the domain runs from zero to infinity. In practice, however, losses are limited by some large amount (such as the total assets of the firm). Often in modeling losses, we ignore this fact because the probability of such an event is extremely small. If the probability of such a loss is sufficiently large to be material, we could apply a limit x to the loss random variable X , and consider the distribution of $X \wedge x = \min(X, x)$. We first introduce a selected set of continuous distributions with support on $(0, \infty)$ and with cumulative distribution function (cdf) denoted by $F(x)$.

In general, using observed data, the principle of parsimony applies. When choosing a model, a simpler model is preferred over a complex one if both models explain a phenomenon adequately. This leads to model selection criteria based on the number of parameters.

Three Important Parametric Families

Distributions can often be organized into related groupings or “families”. Three such families are illustrated in Figures 1–3. Figure 1 shows the four-parameter transformed beta distribution (also known as the *generalized beta* of the second kind, or Pearson type VI distribution)

$$F(x) = \beta\left(\tau, \alpha; \frac{(x/\theta)^\tau}{1 + (x/\theta)^\tau}\right), \quad x > 0 \quad (1)$$

and its special cases where

$$\beta(a, b; x) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \int_0^x t^{a-1}(1-t)^{b-1} dt, \\ a > 0, b > 0, 0 < x < 1 \quad (2)$$

is the incomplete beta function and where

$$\Gamma(\alpha; x) = \frac{1}{\Gamma(\alpha)} \int_0^x t^{\alpha-1} e^{-t} dt, \quad \alpha > 0, x > 0 \quad (3)$$

is the incomplete gamma function with

$$\Gamma(\alpha) = \int_0^\infty t^{\alpha-1} e^{-t} dt, \quad \alpha > 0 \quad (4)$$

There are eight special cases shown in Figure 1. These special cases arise by setting one or two nonscale parameters to 1 or equating pairs of nonscale parameters. The arrows in Figure 1 show the familial relationships. This structured familial approach to distributions is very useful when selecting from among members of the family. For example, given a set of data, one could compare the importance of the parameter τ when comparing the logistic distribution to the inverse Burr distribution using a likelihood-ratio test. Klugman *et al.* [1] use this approach in model selection. Figure 2 shows the transformed (or generalized) gamma distribution with cdf

$$F(x) = \Gamma(\alpha; (x/\theta)^\tau), \quad x > 0 \quad (5)$$

Its special cases are the gamma, Weibull, and exponential distributions. Figure 2 also shows the inverse transformed gamma distribution (also known as the inverse generalized gamma distribution) with cdf

$$F(x) = 1 - \Gamma(\alpha; (\theta/x)^\tau), \quad x > 0 \quad (6)$$

Figure 1 Transformed beta family

Figure 2 Transformed/inverse transformed gamma family

respectively. Its special cases are the corresponding “inverse” versions of the special cases of the transformed gamma distribution.

Another way to relate distributions is examine what happens as parameters approach the limiting values of zero or infinity. This will allow us to relate all distributions shown in Figures 1 and 2. By letting α go to infinity, the transformed gamma distribution is obtained as a limiting case of the transformed beta family. Similarly, the inverse transformed gamma distribution is obtained by letting τ go to infinity instead of α . Because the Burr distribution is a transformed beta distribution with $\tau = 1$, its limiting case is the transformed gamma with $\tau = 1$, which is the Weibull distribution. Similarly, the inverse Burr has the inverse Weibull (see **Dose-Response Analysis; Reliability Growth Testing**) as a limiting case. Finally, letting $\tau = \gamma = 1$ shows that the limiting case for the Pareto distribution is the exponential (and similarly for their inverse distributions). Figure 3 illustrates the limiting and special case relationships.^a

Tails of Continuous Distributions

The tail of a distribution (more properly, the right tail) is the portion of the distribution corresponding

Figure 3 Distributed relationships and characteristics

to large values of the random variable. Understanding large possible loss values is important because these have the greatest impact on the total of risk losses. Distributions that tend to assign higher probabilities to larger values are said to be heavier tailed (*see Default Risk*). The “weight” of the tail can be a relative concept (model A has a heavier tail than model B) or an absolute concept (distributions with a certain property are classified as heavy tailed). When choosing models, tail weight can help narrow the choices or can confirm a choice for a model. Heavy-tailed distributions are particularly important in risk modeling in connection with extreme value theory (*see, for example [2]*).

Classification Based on Moments

The k th raw moment for a continuous random variable that takes on only positive values (such as losses) is given by $\int_0^\infty x^k f(x) dx$. Depending on the probability density function and the value of k , this integral may not exist. One way of classifying distribution is on the basis of how many positive moments exist. It is generally agreed that the existence of all positive moments indicates a light right tail, while the existence of only positive moments up to a certain value (or existence of no positive moments at all) indicates a heavy right tail.

By this classification, the Pareto distribution is said to have a heavy tail and the gamma distribution is said to have a light tail. A look at moment formulas reveals which distributions have heavy tails and which do not, as indicated by the existence of moments. Moment formulas for all distributions considered in this paper are given in Klugman *et al.* [1].

Classification Based on Tail Behavior

One commonly used indication that one distribution has a heavier tail than another distribution with the same mean is that the ratio of the two survival functions diverges to infinity (with the heavier-tailed distribution in the numerator) as the argument becomes large. This classification is based on asymptotic properties of the distributions. The divergence implies that the numerator distribution puts significantly more probability on large values. Note that it is equivalent to examine the ratio of density functions

since

$$\lim_{x \rightarrow \infty} \frac{\bar{F}_1(x)}{\bar{F}_2(x)} = \lim_{x \rightarrow \infty} \frac{\bar{F}_1'(x)}{\bar{F}_2'(x)} = \lim_{x \rightarrow \infty} \frac{f_1(x)}{f_2(x)} \quad (7)$$

where $\bar{F}(x) = 1 - F(x)$ represents the right tail of distribution (*see Operational Risk Modeling; Compliance with Treatment Allocation*).

Classification Based on Hazard Rate Function

The hazard rate function (*see Combining Information; Default Risk; Imprecise Reliability; Hazard and Hazard Ratio; Operational Risk Development*) $h(x) = -\frac{d}{dx} \ln \bar{F}(x)$ also reveals information about the tail of the distribution. Distributions with decreasing hazard are said to have heavy tails and those with increasing hazard rate functions are said to have light tails. The distribution with constant hazard rate, the exponential distribution, has neither an increasing nor a decreasing failure rate. For distributions with (asymptotically) monotone hazard rates, distributions with exponential tails divide the distributions into heavy-tailed and light-tailed distributions.

Comparisons between distributions can be made on the basis of the rate of increase or decrease of the hazard rate function. For example, a distribution has a lighter tail than another if, for large values of the argument, its hazard rate function is increasing at a faster rate.

Classification Based on Mean Excess Function

The mean excess function (*see Potency Estimation; Extreme Values in Reliability*) is given by $e(d) = E[X|X > d]$. It also gives information about tail weight. If the mean excess function is increasing in d , the distribution is considered to have a heavy tail. If the mean excess function is decreasing in d , the distribution is considered to have a light tail. Comparisons between distributions can be made on the basis of the rate of increase or decrease of the mean excess function. For example, a distribution has a heavier tail than another if, for large values of the argument, its mean excess function is increasing at a lower rate.

The mean excess loss function and the hazard rate are closely related. If the hazard rate is a decreasing function, then the mean excess loss function $e(d)$ is

an increasing function of d . Similarly, if the hazard rate is an increasing function, then the mean excess loss function is a decreasing function. It is worth noting (and is perhaps counterintuitive, however), that the converse implication is not true.

There is a second relationship between the mean excess loss function and the hazard rate. The limiting behavior of the mean excess loss function as $d \rightarrow \infty$ may be ascertained using L'Hôpital's rule. We have

$$\lim_{d \rightarrow \infty} e(d) = \lim_{d \rightarrow \infty} \frac{1}{h(d)} \quad (8)$$

as long as the indicated limits exist. These limiting relationships may be useful if the form of $F(x)$ is complicated.

Models for the Number of Losses: Counting Distributions

We now review a class of counting distributions; i.e., discrete distributions with probabilities only at the points $0, 1, 2, 3, 4, \dots$. In a risk context, counting distributions can be used to describe the number of losses or the number of loss-causing events. With an understanding of both the number of losses and the size of losses, we can have a deeper understanding of a variety of issues surrounding risk exposure than if we have only historical information about the total of all losses experienced. Also, the impact of risk mitigation strategies that address either the frequency of losses or the size of losses can be better understood. Finally, models for the number of losses are fairly easy to obtain and experience has shown that the commonly used frequency distributions perform well in modeling the propensity to generate losses. We restrict ourselves to a limited, but quite flexible, family of discrete distributions. Johnson *et al.* [3] provides a comprehensive review of such distributions.

We now formalize some of the notations that will be used for models for discrete phenomena. The probability function (pf) p_k denotes the probability that exactly k events (such as losses) occur. Let N be a random variable representing the number of such events. Then

$$p_k = \Pr(N = k), \quad k = 0, 1, 2, \dots \quad (9)$$

The probability generating function (pgf) of a discrete random variable N with pf p_k is $P(z) = E(z^N) =$

$\sum_{k=0}^{\infty} p_k z^k$. The probabilities are easily obtained from the pgf.

The $(a, b, 0)$ Class

Let p_k be the pf of a discrete random variable. It is a member of the $(a, b, 0)$ class of distributions, provided there exist constants a and b such that

$$p_k = \left(a + \frac{b}{k}\right) p_{k-1}, \quad k = 1, 2, 3, \dots \quad (10)$$

This recursive relation describes the relative size of successive probabilities in the counting distribution. The probability at zero, p_0 , can be obtained from the recursive formula because the probabilities must sum to 1. This boundary condition, together with the recursive formula, will uniquely define the probabilities. The $(a, b, 0)$ class of distributions is a two-parameter class, the two parameters being a and b . By substituting in the pf for each of the Poisson (with pgf $P(z) = e^{\lambda(z-1)}$), binomial (with pgf $P(z) = \{1 + q(z-1)\}^m$), and negative binomial (with pgf $P(z) = \{1 - \beta(z-1)^{-r}\}$) distributions on the left-hand side of the recursion, it can be seen that each of these three distributions satisfies the recursion and that the values of a and b are as given in Table 1. In addition, the table gives the value of p_0 , the starting value for the recursion. In Table 1 the geometric distribution, the one-parameter special case ($r = 1$) of the negative binomial distribution, is also present. These are the only possible distributions satisfying this recursive formula.

The $(a, b, 1)$ Class

Frequently, the four distributions discussed earlier do not adequately describe the characteristics of some data sets encountered in practice, because the distributions in the $(a, b, 0)$ class cannot capture the shape of observed data. For loss count data,

Table 1 The $(a, b, 0)$ class

Distribution	a	b	p_0
Poisson	0	λ	$e^{-\lambda}$
Binomial	$-\frac{q}{1-q}$	$(m+1)\frac{q}{1-q}$	$(1-q)^m$
Negative binomial	$\frac{\beta}{1+\beta}$	$(r-1)\frac{\beta}{1+\beta}$	$(1+\beta)^{-r}$
Geometric	$\frac{\beta}{1+\beta}$	0	$(1+\beta)^{-1}$

the probability at zero is the probability that no losses occur during the period under study. When the probability of occurrence of a loss is very small (as is usually the case), the probability at zero has the largest value. Thus, it is important to pay special attention to the fit at this point. Similarly, it is possible to have situations in which there is less than the expected number, or even zero, occurrences at zero. Any adjustment of the probability at zero is easily handled by modifying the Poisson, binomial, and negative binomial distributions at zero.

A counting distribution is a member of the $(a, b, 1)$ class of distributions provided there exist constants a and b such that

$$p_k = \left(a + \frac{b}{k}\right) p_{k-1}, \quad k = 2, 3, 4, \dots \quad (11)$$

Note that the only difference from the $(a, b, 0)$ class is that the recursion begins at p_1 rather than at p_0 . This forces the distribution from $k = 1$ to $k = \infty$ to be proportional to the corresponding $(a, b, 0)$ distribution. The remaining probability is at $k = 0$ and can take on any value between 0 and 1.

We distinguish between the situations in which $p_0 = 0$ and those where $p_0 > 0$. The first subclass is called the *truncated* (more specifically, zero-truncated (ZT) distributions. The members are the ZT Poisson, ZT binomial, and ZT negative binomial (and its special case, the ZT geometric) distributions. The second subclass will be referred to as the zero-modified (ZM) distributions because the probability is modified from that for the $(a, b, 0)$ class.

The $(a, b, 1)$ class admits additional distributions. The (a, b) parameter space can be expanded to admit an extension of the negative binomial distribution to include cases where $-1 < r \leq 0$. For the $(a, b, 0)$ class, the condition $r > 0$ is required. By adding the additional region to the sample space, the “extended” truncated negative binomial (ETNB) distribution has parameter restrictions $\beta > 0, r > -1, r \neq 0$.

For the ETNB, the parameters and the expanded parameters space are given by

$$\begin{aligned} a &= \frac{\beta}{1 + \beta}, \quad \beta > 0, \\ b &= (r - 1) \frac{\beta}{1 + \beta}, \quad r > -1, \quad r \neq 0 \end{aligned} \quad (12)$$

When $r \rightarrow 0$, the limiting case of the ETNB is the logarithmic distribution with pf

$$p_k = \frac{[\beta/(1 + \beta)]^k}{k \ln(1 + \beta)}, \quad k = 1, 2, 3, \dots \quad (13)$$

and pgf

$$P(z) = 1 - \frac{\ln[1 - \beta(z - 1)]}{\ln(1 + \beta)} \quad (14)$$

The ZM logarithmic distribution is created by assigning an arbitrary probability at zero and adjusting the remaining probabilities proportionately.

It is also interesting that the special extreme case with $-1 < r < 0$ and $\beta \rightarrow \infty$ is a proper distribution, sometimes called the Sibuya distribution. It has pgf $P(z) = 1 - (1 - z)^{-r}$, and no moments exist. Distributions with no moments are not particularly interesting for modeling loss numbers (unless the right tail is subsequently modified) because an infinite number of losses are expected. If this is the case, the risk manager should be fired!

There are no other members of the $(a, b, 1)$ class beyond those discussed above. A summary is given in Table 2.

Compound Frequency Models

A compound frequency larger class of distributions can be created by the processes of compounding any two discrete distributions. The term *compounding* reflects the idea that the pgf of the new distribution $P(z)$ is written as $P(z) = P_N[P_M(z)]$, where $P_N(z)$ and $P_M(z)$ are called the *primary* and *secondary distributions*, respectively.

The compound distributions arise naturally as follows. Let N be a counting random variable with pgf $P_N(z)$. Let $M_1, M_2, \dots$ be identically and independently distributed (i.i.d.) counting random variables with pgf $P_M(z)$. Assuming that the M_j s do not depend on N , the pgf of the random sum $S = M_1 + M_2 + \dots + M_N$ (where $N = 0$ implies that $S = 0$) is $P_S(z) = P_N[P_M(z)]$.

In risk contexts, this distribution can arise naturally. If N represents the number of loss-causing events and $\{M_k; k = 1, 2, \dots, N\}$ represents the number of losses (errors, injuries, failures, etc.) from the individual events, then S represents the total number of losses for all such events. This kind of interpretation is not necessary to justify the use of

Table 2 The $(a, b, 1)$ class

Distribution	$p0$	a	b	Parameter space
Poisson	$e^{-\lambda}$	0	λ	$\lambda > 0$
ZT Poisson	0	0	λ	$\lambda > 0$
ZM Poisson	Arbitrary	0	λ	$\lambda > 0$
Binomial	$(1-q)^m$	$-\frac{q}{1-q}$	$(m+1)\frac{q}{1-q}$	$0 < q < 1$
ZT binomial	0	$-\frac{q}{1-q}$	$(m+1)\frac{q}{1-q}$	$0 < q < 1$
ZM binomial	Arbitrary	$-\frac{q}{1-q}$	$(m+1)\frac{q}{1-q}$	$0 < q < 1$
Negative binomial	$(1+\beta)^{-r}$	$\frac{\beta}{1+\beta}$	$(r-1)\frac{\beta}{1+\beta}$	$r > 0, \beta > 0$
ETNB	0	$\frac{\beta}{1+\beta}$	$(r-1)\frac{\beta}{1+\beta}$	$r > -1, \beta > 0$
ZM ETNB	Arbitrary	$\frac{\beta}{1+\beta}$	$(r-1)\frac{\beta}{1+\beta}$	$r > -1, \beta > 0$
Geometric	$(1+\beta)^{-1}$	$\frac{\beta}{1+\beta}$	0	$\beta > 0$
ZT geometric	0	$\frac{\beta}{1+\beta}$	0	$\beta > 0$
ZM geometric	Arbitrary	$\frac{\beta}{1+\beta}$	0	$\beta > 0$
Logarithmic	0	$\frac{\beta}{1+\beta}$	$-\frac{\beta}{1+\beta}$	$\beta > 0$
ZM logarithmic	Arbitrary	$\frac{\beta}{1+\beta}$	$-\frac{\beta}{1+\beta}$	$\beta > 0$

a compound distribution. If a compound distribution fits data well, that may be enough justification itself.

Consider the case where both M and N have the Poisson distribution. Determine the pgf of this distribution. This distribution is called the *Poisson–Poisson* or *Neyman Type A distribution*. Let $P_N(z) = e^{\lambda_1(z-1)}$ and $P_M(z) = e^{\lambda_2(z-1)}$. Then

$$P_S(z) = e^{\lambda_1[e^{\lambda_2(z-1)}-1]} \quad (15)$$

The Poisson–logarithmic distribution can be shown to be a negative binomial distribution. Thus the Poisson–logarithmic distribution does not create a new distribution beyond the $(a, b, 0)$ and $(a, b, 1)$ classes. Another combination that does not create a new distribution beyond the $(a, b, 1)$ class is the compound geometric distribution where both the primary and secondary distributions are geometric. The resulting distribution is a ZM geometric distribution.

Finally it is easy to show that adding, deleting, or modifying the probability at zero in the secondary distribution does not add a new distribution because it is equivalent to modifying the parameter θ of the primary distribution. This means that, for example, a Poisson primary distribution with a Poisson, ZT Poisson, or ZM Poisson secondary distribution will

still lead to a Neyman Type A (Poisson–Poisson) distribution.

Relationships among discrete distributions are shown in Table 3.

Recursive Calculation of Compound Probabilities

The probability of exactly k losses can be written as

$$\Pr(S = k) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \Pr(M_1 + \cdots + M_n = k) \quad (16)$$

$$\Pr(N = n)$$

Letting $g_n = \Pr(S = n)$, $p_n = \Pr(N = n)$, and $f_n = \Pr(M = n)$, this is rewritten as

$$g_k = \sum_{n=0}^{\infty} p_n f_k^{*n} \quad (17)$$

where f_k^{*n} , $k = 0, 1, \dots$, is the n -fold convolution of the function f_k , $k = 0, 1, \dots$, that is, the probability that the sum of n random variables that are each i.i.d. with probability function f_k will take on value k .

When $P_N(z)$ is chosen to be a member of the $(a, b, 0)$ class, the recursive formula

$$g_k = \frac{1}{1 - af_0} \sum_{j=1}^k \left(a + \frac{bj}{k} \right) f_j g_{k-j},$$

can be used to evaluate probabilities.

This recursion has become known as *the Panjer recursion* (see **Comonotonicity**) after its introduction as a computational tool for obtaining numerical values of the distribution of aggregate losses by Panjer [4]. Its use here is numerically equivalent to its use for aggregate losses where the secondary distribution is the distribution of loss sizes. This result was generalized by Sundt and Jewell [5] to the case of the primary distribution being a member of the $(a, b, 1)$ class:

$$g_k = \frac{[p_1 - (a + b)p_0]f_k + \sum_{j=1}^k \left(a + \frac{bj}{k}\right) f_j g_{k-j}}{1 - af_0}, \quad k = 1, 2, 3, \dots \quad (19)$$

Dose–Response Analysis

One component of quantitative risk assessment is the search for and the study of the relationship between exposure and effect. Proof of the existence of a *dose–response relationship* is a basic element for the proof of a cause–effect relationship between the exposure to an agent and the occurrence of an effect (see **Causality/Causation**). As a consequence, *dose–response assessment* is a key element in carcinogenic risk assessment. It is part of the hazard characterization step, when the four-step approach to risk assessment is adopted (hazard identification, hazard characterization, exposure assessment, and risk characterization).

The purpose of a dose–response analysis in quantitative risk assessment is the detection, characterization, and quantification of a relationship $D \rightarrow Y(D)$ between the critical effect Y on human health and environment and the dose D of the hazardous exposure. Establishment of a dose–response relationship requires support from life science (biology, medicine, and environmental science), statistical science, and risk management. Life sciences provide both, knowledge for the appropriate choice of the *dose–response model* and the *dose–response data* from appropriate experiments or empirical observations. Statistical science applies methods of statistical inference for estimating effect parameters, characterizing their uncertainty and prediction. Risk assessors and risk managers select in cooperation with the former two disciplines the appropriate risk metric R as function of the basic effect measure $Y: D \rightarrow Y(D) \rightarrow R(D)$.

Dose–Response Data

Dose data are of quantitative nature and describe amounts or concentrations of the agent in the individual after exposure. Therefore dose is a numerical value describing the exact amount of the agent entering the organism or acting at the target site. An agent can enter an organism at various instances (environmental, accidental, by purpose, etc.), through various routes (inhalation, dermal, oral, etc.) before it is deposited at a site of action and before it is metabolized, may induce production of other hazardous substances (see **What are Hazardous Materials?**), and finally may be excreted. As a consequence, one

has to specify nature (applied dose, internal dose, delivered dose, etc.) of the dose. Difficulties in determining the delivered dose, also called *target organ dose*, were identified in [1] by five questions:

- Is dose expressed as an environmental concentration, applied dose, or delivered dose to the target organ?
- Is dose expressed in terms of a parent compound, one or more metabolites, or both?
- Is the impact of dose patterns and timing significant?
- Is there a conversion from animal to human doses, when animal data are used?
- Is a conversion metric between routes of exposure necessary and appropriate?

With respect to the first question one should emphasize that the goal of dose modeling is to estimate, to the extent possible, the delivered dose of the active agent at the target organ or target cell. When direct measurement is not possible, this could be achieved using pharmacokinetic models when sufficient and confident knowledge is available; otherwise, dose–response modeling often proceeds with less specific dose metrics, e.g., the average daily dose of the agent. Similarly, kinetic modeling has been very helpful to determine dose metrics when metabolic pathways have been known as *relevant for the risk assessment*. Interspecies and intraspecies adjustments of the dose and route-to-route extrapolation may use physiologically based models to calculate a dose parameter. For more details on how to deal with these questions, all of which address issues of extrapolations in a more broad sense, see the overview given by Cogliano [2].

Response data characterize the toxic endpoints. Multiplicity of adverse effects may be handled by defining primary and secondary toxic endpoints or through agreement upon the most critical endpoint using information on severity and relevance. Otherwise, statistical methods for multiple testing have to be considered. In cancer risk assessment, tumor incidence data and tumor specific mortality data have been the basic endpoints of response for a dose–response assessment. Response can be analyzed directly by setting the risk measure R equal to the effect measure Y or by defining a risk measure as a function $R(D) = R(Y(D))$ of the observations.

Depending on the scale of the endpoints one can distinguish three response types:

Quantal

$R(D) = P(Y(D) = 1)$: probability of the occurrence of the adverse health event: e.g., tumor, liver damage, renal failure, and death.

Categorical

$R_x(D) = P(Y(D) \geq x)$: probability of the occurrence of an adverse health event at least as serious as a given category, say, x , e.g., adverse event of at least grade 3.

Quantitative

$R(D) = Y(D)$: level of an adverse health outcome observed on a continuous metric scale that is either increasing or decreasing with dose e.g., blood cell counts and weight decay.

Response can be analyzed directly as above or related to a reference response, e.g., the background response $R(0)$. *Additional risk* is defined as $R_{\text{add}}(D) = R(D) - R(0)$. *Extra risk* is defined as $R_{\text{extra}}(D) = [R(D) - R(0)]/[R_{\text{max}} - R(0)]$ where R_{max} is the maximum possible risk level of the study. In case of quantal response $R_{\text{max}} = 1$; in case of quantitative response one may chose $R_{\text{max}} = \max(y_{ij} | i = 1, \dots, I; j = 1, \dots, n_i)$; y_{ij} defined next.

Empirical *dose–response data* are generated in experimental or observational studies. In a controlled experiment, the exposure dose is applied to the individual experimental unit and varies on the basis of the experimental design. The effect size or the occurrence of an effect is recorded. In observational studies, both the individual’s exposure dose and the effect size, or the occurrence of an effect are recorded. It is important to note that a variation of the dose over some dose range takes place. In both cases, data are of the following type:

A total of N individuals is assigned to a set of $I + 1$ groups such that n_i individuals are assigned the dose d_i , respectively; $i = 0, 1, \dots, I$, where $I \geq 2$ doses are arranged in an increasing order, $0 < d_1 < d_2 < \dots < d_I$, and where $d_0 = 0$ denotes the control group, $n_i \geq 0$ and $\sum_{i=0}^I n_i = N$. Each among the n_i individuals exposed to dose d_i exhibits a response y_{ij} , $j = 1, \dots, n_i$, $i = 0, 1, \dots, I$. The dose–response data are then represented as $\{(y_{ij}, d_i), j = 1, \dots, n_i, i = 0, 1, \dots, I\}$. It should be noted that, in a strict sense, dose–response data require at least three groups, two dose groups and a control or three dose groups. The response variable Y , with values y_{ij} for subject j in group i could be an endpoint of continuous, categorical, or dichotomous (presence or absence of a target effect) scale. When considering tumor incidence in a carcinogenesis experiment the response would be either $y_{ij} = 1$ (tumor) or $y_{ij} = 0$ (no tumor). Those data are summarized as $\{d_i, n_i, p_i, i = 0, 1, \dots, I\}$ where $r_i = \sum_{j=1}^{n_i} y_{ij}$ denotes the number of tumors in dose group i and $p_i = r_i/n_i$ is the proportion of tumor-bearing individuals. An example of tumor incidence data is given in Table 1.

Qualitative Dose–Response Analysis

Statistical inference for dose–response data can be obtained through a qualitative or a quantitative methodology depending on whether functional information is used to select the dose–response model or not. If no functional information on dose–response is postulated, one may analyze the dose–response data (d_i, y_{ij}) using multiple hypotheses testing with the null hypothesis

$$H_0: F_0 = F_1 = \dots = F_I \quad (1)$$

where “ $F_i = F_j$ ” describes the fact that the two groups with doses d_i and d_j provide the same effect.

Table 1 Original and fitted data from a dose–response experiment on cancer incidence with quantal response when the Weibull model (see Figure 1) was applied

Dose group	Dose d_i	Sample size n_i	Observed incidence r_i	Observed proportion p_i	Expected incidence	Expected proportion
1	0.0	86	2	0.023	1.67	0.019
2	0.001	50	1	0.02	2.52	0.051
3	0.01	50	9	0.18	6.92	0.138
4	0.1	45	18	0.40	18.78	0.417

A qualitative dose-response model is defined through the alternative H_1 , e.g., a trend alternative

$$H_1 : F_0 \leq F_1 \leq \dots \leq F_I \quad (2)$$

where $F_i \leq F_j$ describes the fact that the response of dose d_j is larger than at dose d_i . If one assumes, e.g., Gaussian normally distributed responses $Y_{ij} \sim N(\mu_i, \sigma_i^2)$, the alternative of monotone increasing trend in the means is given as $H_0 = \mu_0 \leq \mu_1 \leq \dots \leq \mu_I$ with $\mu_0 < \mu_I$. If the responses are proportions p_i and if the alternative $H_1 = p_0 \leq p_1 \leq \dots \leq p_I$ with $p_0 < p_I$ is of interest one usually applies the Cochran-Armitage trend test (see [3]). For situations where a monotone alternative is no more tested, but a downturn of the dose-response relationship is possible, the so-called umbrella alternative is recommended $H_0: \mu_0 \leq \mu_1 \leq \dots \mu_i^* \geq \mu_{i+1}^* \geq \dots \geq \mu_I$, where the * indicates the dose location of downturn.

Dose-Response Models

If functional information on dose-response is available, a dose-response model can be selected from standard models used for quantal dose-response analysis [4]:

Probit

$$R(d) = p + (1 - p) \cdot \Phi(a + b \ln d)$$

Logit

$$R(d) = p + (1 - p) \cdot [1 + \exp(-(a + b \ln d))]^{-1}$$

Weibull

$$R(d) = p + (1 - p) \cdot (1 - \exp(-bd^k))$$

Gamma multihit

$$R(d) = p + (1 - p) \cdot \int_0^d [b^n t^{n-1} / \Gamma(n)] \cdot \exp(-bt) dt$$

One hit

$$R(d) = p + (1 - p) \cdot [1 - \exp(-bd)]$$

Multistage

$$R(d) = p + (1 - p) \cdot \left[1 - \exp\left(-\sum_{i=0}^K a_i d^i\right) \right]$$

when Φ stands for the Gaussian distribution and Γ for the γ function.

For continuous response analysis, a family of nonlinear regression models for the mean response $\mu_i = E[Y_i]$ as a function of dose d_i , has been proposed [5]; also see [6] for a set of models for mutagenic response. For the case of discrete count data (e.g., number of defect cells) one usually applies log-linear regression models, which are part of the larger class of statistical generalized linear models. (For models with a threshold see **Threshold Models**.)

Models of the type described above have been termed *empirical models* or *curve fitting models* because of their origin as purely statistical models (e.g., the probit or logit model), or because of only limited relationship to biological processes (e.g., the multihit model).

The decision on the shape of the dose-response analysis is often based on a judgment of the mechanism for the substance under evaluation. The mechanism of genotoxicity is most prominent in carcinogenic risk assessment. Nongenotoxic carcinogens are dealt with using a threshold type approach where an estimate of the “threshold” is obtained and safety factors are applied for the extrapolation to low doses, whereas genotoxic carcinogens are dealt with using a nonthreshold dose-response relationship and a mathematical dose-response model is used for low dose extrapolation.

These models are in contrast to biologically based models or mechanistic models usually built as stochastic mathematical models based on biological information and knowledge of mode of action of the agent in the organism. Most prominent examples in cancer risk assessment are multistage carcinogenesis models and the two-stage model of clonal expansion; see e.g., the review of [7].

A large family of empirical models can be defined using the “tolerance dose distribution” concept. This is a general statistical approach for establishing dose-response functions $P(d)$. A toxic effect is considered to occur at dose d if the individual’s resistance to the substance is broken at that dose. The excess risk $P(d)$ is then modeled as the probability that the tolerance dose of an individual is less or equal to d :

$$\text{Prob}(\text{tolerance} \leq d) = P(d) \quad (3)$$

where $P(d)$ may be any monotone increasing function with values between 0 and 1. General classes of quantal dose-response models are of the form $P(d) = p + (1 - p)F(g(d, \beta))$, where the “inner”

dose function $g(d, \beta)$ can be taken from a flexible class of transformations and is parameterized by β .

Quantal dose–response models listed above can be extended to address age-dependent incidence $P(t, d)$ by incorporating straightforwardly the time (or age) of the investigated individual into the model which previously had not been time dependent [4]. Such, one can define

Probit

$$P(t, d) = p + (1 - p) \cdot \Phi(a + b \ln d + c \ln t)$$

Logit

$$P(t, d) = p + (1 - p) \cdot [1 + \exp(-(a + b \ln d + c \ln t))]^{-1}$$

Weibull

$$P(t, d) = p + (1 - p) \cdot (1 - \exp(bd^m t^k))$$

Multihit

$$P(t, d) = p + (1 - p) \cdot \int_0^{dt} [b^n u^{n-1} / \Gamma(n)] \exp(-bu) du$$

Multistage

$$P(t, d) = p + (1 - p) \cdot \left\{ 1 - \exp \left[- \sum_{i=0}^K a_i d^i \right] b t^K \right\}$$

More generally, an age-dependent tumor incidence model can be defined using a nonparametric proportional hazard function $\lambda^T(t, d)$ of the time-to-tumor T. The practical estimation of $\lambda^T(t, d)$ from carcinogenesis bioassay data requires statistical methodology of censored survival times and consideration of competing risks since occurrence of the event of interest competes with death, when aging is allowed [8].

Quantitative Dose–Response Analysis

Dose–response analysis aims both at estimating the risk at a particular exposure level and the exposure level associated with a particular risk. A quantitative analysis of the risk of a detrimental effect affecting the individual and denoted R , assumes that exposure can be quantified in terms of a dose $D = d$, and the existence of a functional relationship F between R and D of the general form

$$R = R(D) = F(D; t, x, \beta) \quad (4)$$

where t denotes the time of the observation or the occurrence of the effect, x denotes characteristic(s) of the individual, and β denotes the parameter(s) specifying the functional relationship F . The two aims of a dose–response analysis can then be specified as

1. Estimation of F such that one can calculate the risk $R(d)$ for each given dose $d : \hat{R}(d) = F(d; t, x, \hat{\beta})$.
2. Estimation of F such that one can calculate the dose $D(r)$ for each given risk level $r : \hat{D}(r) = F^{-1}(r; t, x, \hat{\beta})$.

where $\hat{\beta}$ denotes the estimate of the model parameter β in the function F and where F^{-1} denotes the inverse of the function F (existence assumed). Therefore, the analysis of a dose–response relationship proceeds in two steps. First, the dose relationship F has to be established using a mathematical modeling approach. Second, the function F has to be specified completely through statistical estimation. Therefore, usually maximum-likelihood methods are applied to estimate the model parameter β such that $\hat{F}$ as function of $\hat{\beta}$ is also a maximum-likelihood estimate.

Maximum-likelihood estimation for quantal data grounds on the binomial distribution of the number of responses $R_i = r_i$ at the dose level d_i : $R_i \sim \text{Binomial}(n_i, p_i)$ where p_i is defined in the dose–response model. For continuous data a general model is $R(d) = \mu(d) + \varepsilon$, where μ denotes a predictor and $\varepsilon \sim N(0, \sigma^2)$ the error term [3]. Asymptotic theory of inference is well established for the quantal dose–response model and it provides confidence interval estimates, resulting from the asymptotic properties of maximum likelihood estimates which are consistent, unbiased, and efficient (minimal variance) with convergence to a Gaussian distribution. Fisher information theory is used to derive the variance–covariance estimates from which asymptotic confidence intervals can be calculated. Application of Fieller’s theorem then allows the calculation of confidence intervals for functions of model parameters. (For the extrapolation to low doses see **Low-Dose Extrapolation** and **Benchmark Dose Estimation** or [9] and [10].) Recommended steps for the dose–response analysis are as follows:

- identify the kinds of data available on dose and response;

- select the response and dose metric for assessment;
- present and discuss the results of the dose–response assessment; and
- explain the results of the analyses in terms of quality of data available.

Example

A dose–response analysis is illustrated with data on the incidence of hepatocellular carcinoma and adenoma after exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (see **Health Hazards Posed by Dioxin**) from an experiment with one control and three dose groups exposed to doses $d_i, i = 1, \dots, 3$ and quantal responses $p_i = r_i/n_i, i = 1, \dots, 3$ as shown in columns 1–5 of Table 1 (see the lower part of Table 2 in reference [11]). There is a statistically significant trend of increasing tumor incidence from 2% in the control group to 40% in the highest dose group (Cochran–Armitage test for linear trend: $p = 7.6 \times 10^{-10}$). When selecting the Weibull model $R(d) = p + (1 - p)(1 - \exp(-bd^k))$ with the three parameters p = background response, b = slope, and k = shape for a quantitative dose–response analysis one obtains the maximum-likelihood estimates $\hat{p} = 0.0194$ (0.0134), $\hat{b} = 2.0934$ (1.0834), and $\hat{k} = 0.6044$ (0.1589) with standard errors of the parameter estimates in parentheses. The fitted curve $\hat{R}(d) = 0.0194 + 0.9806 [1 - \exp(2.0934 \times d^{0.6044})]$ is shown in Figure 1. This evaluation was

Figure 1 Fit of the Weibull model $R(d) = p + (1 - p) \cdot (1 - \exp(-bd^k))$ to the data of Table 1 using USEPA software *BMDs*. Location of the BMD and 95% – BMDL for the extra risk to specified BMR of 10% are indicated in the graphic. BMD is estimated as 0.00711 and the BMDL as 0.00198

performed using the USEPA software *BMDs*, which allows the estimation of the benchmark dose (BMD) and the 95% lower benchmark dose limit (BMDL) indicated in Figure 1.

Change Point Analysis

Dynamic Financial Analysis

Dynamic financial analysis (DFA) is *dynamic* in the sense that it incorporates stochastic, or random, elements to reflect a variety of possible outcomes. The term *financial* reflects the fact that DFA incorporates, for insurers, both the underwriting side of the business and the investment side of operations; for any firm it involves combining assets and liabilities to project the aggregate financial position of the organization. The term *analysis* reflects the fact that this approach models the complex interrelationships involved in an organization. Other terms used to describe this process include dynamic financial condition analysis, dynamic capital adequacy testing, or dynamic solvency testing.

A DFA model starts with the current financial position of the organization. The key elements that impact operations are modeled mathematically, incorporating random elements where appropriate. A DFA model simulates the results of hundreds or thousands of iterations, and the financial condition of the firm is determined for each set of results. The relationship between assets and liabilities for each iteration shows whether the firm will be solvent or in financial difficulty in future years. The output from DFA is the distribution of potential financial results for the next few years.

DFA is used for a variety of reasons, including solvency regulation (*see Solvency*), assigning ratings to an organization, evaluating the impact of a change in operations, and determining the value of an organization for a merger or acquisition. When used for solvency regulation, the output from DFA is used to determine how frequently the organization will encounter financial difficulties and how severe those difficulties will be. Regulators utilize DFA to determine which insurers should be put under surveillance, whether additional capital is required for the firm, or if restrictions on operations should be instituted. DFA can alert regulators to potential problems before the firm becomes insolvent. Rating agencies utilize the results of DFA in assigning ratings to organizations, with those least likely to encounter financial difficulties obtaining the highest ratings and those most likely to become impaired receiving lower ratings.

Firms can often respond to potential ratings by changing their operations or capitalization level to reduce the risk of financial impairment and improve their rating. In this event, DFA helps to reduce the number of financial impairments. Organizations also use DFA to evaluate different operational strategies before deciding changes in its operations. DFA is commonly used to evaluate different reinsurance (*see Optimal Risk-Sharing and Deductibles in Insurance; Reinsurance*) contracts, to determine whether to enter a new geographical area or market, or to determine the appropriate growth strategy. When used in merger and acquisition situations, DFA indicates the financial position of the organization under a variety of different economic conditions in order to determine the value of the firm.

Other financial planning approaches include forecasting, sensitivity analysis, and scenario testing. Under forecasting, a firm develops a financial plan based on the most likely conditions to develop. This approach uses a single plan as a benchmark for future performance. Frequently, firms then focus on deviations between the actual results that develop and the financial plan, as if the plan represents what should have happened and any difference resulting from something that went wrong. However, reliance on a single plan does not reflect the uncertainty that is inherent in any business operation. A variation of the single plan approach is to develop three forecasts, representing an optimistic view, a realistic view, or a pessimistic view of future developments. This approach reflects the uncertainty inherent in future developments, but there is no probability estimates associated with each set of results, so there is no way to know how likely each of the forecasts is expected to occur.

Sensitivity analysis also reflects the uncertainty associated with forecasting. Under sensitivity analysis, each important variable that affects operations is varied from the realistic estimate (the base case) to the optimistic and pessimistic values, and the financial forecast is recalculated to reflect this variation. Each variable is changed one at a time, with all other variables being held at the base case level. Sensitivity analysis shows which variables have the greatest impact on operations, so that the firm can focus on generating accurate estimates of these values and can try controlling the variation. However, by restricting the changes to one variable at a time, the range of

uncertainty that is inherent in the forecast is restricted unrealistically.

Scenario testing (*see* **Scenario-Based Risk Management and Simulation Optimization; Actuary**) considers the combined impact of changing a number of variables simultaneously by determining financial forecasts based on a few situations that can reasonably be expected to occur in concert. For example, one scenario could involve interest rates increasing by 100 basis points, equity markets declining by 5%, and unemployment rates increasing by 0.5%. Another scenario could involve interest rates increasing by 200 basis points, equity markets declining by 10%, and unemployment rates increasing by 1.5%. These changes represent realistic relationships among these variables. Several scenarios are developed, and the financial results are determined on the basis of each scenario. A firm's ability to remain financially healthy in each scenario is then evaluated. Although scenario analysis does reflect relationships among variables that are important to a firm's operations, there are several problems with this approach. First, scenario testing considers only a few situations of the many that could occur. This approach gives no indication about the impact of other potential situations. Secondly, there is no information about the likelihood of any particular scenario developing, so it is impossible to evaluate whether a firm's weak financial condition in a particular scenario is a serious problem or not.

DFA, if applied properly, can provide much more valuable information about the financial condition of a firm than forecasting, sensitivity analysis, or scenario testing. The financial condition of the firm under a wide variety of potential developments can be determined, and the likelihood of each set of outcomes can be measured. For example, interest rates could vary over a range of several hundred basis points in the iterations that are run. Each change in interest rates would be associated with a particular change in equity returns, unemployment levels, and any other variable included in the model. The results of the DFA would provide not only the impact of the developments, but the likelihood as well. If the firm is only financially impaired in 1 of the 10 000 iterations, then regulators and the management may not be particularly concerned about that situation. However, if the firm faces financial difficulty in 500 of those 10 000 iterations, and the cause in most cases is a significant increase in interest rates, then steps to reduce interest rate exposure should be considered.

Although DFA is a much more valuable tool than other financial planning techniques, developing a DFA model requires extensive effort. Organizations often spend a year or more, with a number of people working together, to develop a useable DFA model. Consulting firms and large financial services organizations have built these models, but in almost all cases the organization considers the model to be proprietary and will not share the model, or even the details about how the model works, with others. Consulting firms that perform DFA projects for clients will provide the results, but not the model to the customer. One exception to this approach is the public access DFA model known as *Dynamo* developed by Pinnacle Actuaries for property-liability insurers, which is available at no charge on their web site: www.pinnacleactuaries.com. This model is representative of most other DFA models, and can be used as an example of how a DFA model functions.

All DFA models are based on a number of key assumptions that govern how the values of future financial measures are determined. One critical assumption is the interest rate generator (*see* **Asset-Liability Management for Life Insurers**). DFA models tend to use one or more of the popular term structure models in finance (*see* Cairns [1] for a description of these models). Another is the inflation generator (*see* **Asset-Liability Management for Nonlife Insurers**). Inflation can be determined as a function of the nominal interest rate, or as a separately determined value that is then combined with the real interest rate to obtain the nominal rate. Stock returns are modeled on the basis of a single distribution, commonly the lognormal, or on the basis of a regime switching model [2]. The other key assumption for property-liability insurers is catastrophe claims. Some DFA models include an internal catastrophe loss generator (*see* **Insurance Pricing/Nonlife**); the number of catastrophes can be determined on the basis of Poisson distribution and the size of the catastrophe based on a lognormal distribution. More commonly, DFA models rely on one of the catastrophe modeling specialists (such as applied insurance research (AIR), risk management solutions (RMS), or EQECAT) to provide company specific values for catastrophe losses for a large number of simulations that are then incorporated into the DFA model.

The output from a DFA run depends on the parameters for each component. The parameters can

be determined from historical data that is generally updated annually (equity returns) from current values [such as using the contemporary yield curve (*see Solvency; Structured Products and Hybrid Securities*) in an arbitrage interest rate model (*see Multistate Models for Life Insurance Mathematics*)] or based on expert opinion about future conditions (catastrophe models that predict that climate change will affect storm severity). As the objective of a DFA model is to model potential future values, care needs to be taken to assure that the model is not being parameterized to generate historical loss patterns if conditions have changed significantly.

Dynamo has several interrelated modules that interact to generate the results. One module generates the underwriting gains and losses of the insurer. Key inputs to this module are the number of policies in force, premium levels, current loss frequency and severity, loss reserves, expected growth rates, and the current segment of the underwriting cycle the industry is in. Historically, the insurance industry fluctuates between soft markets, where competitive pressure keeps premium levels low (and underwriting losses high) and hard markets, where companies face less competitive pressure on rates. Stochastic variables are used to generate the future loss frequency and inflation, which then impact both loss severity and loss development. The policy growth target is applied to a stochastic model of the underwriting cycle that determines the premium level needed to achieve the planned growth. In soft markets, premium levels need to be restrained or reduced in order to increase the market share. In hard markets, premium levels can be raised in line with policy costs and insurers can still grow in the market share. The interaction of the premium levels charged to achieve growth, loss reserve development, and loss costs based on the projected loss frequency and severity determines the underwriting profitability of the insurer, except for catastrophic losses.

Another module determines the catastrophic losses the insurer incurs each year. In the first step, the number of catastrophes (which is defined as industry wide losses in excess of \$25 million) is determined based on a Poisson distribution. A uniform distribution is used to establish a focal point (by state) for each catastrophe determined from the first step. This allocation is based on historical patterns for natural disasters. Once the state that is determined to be the focal point for a catastrophe is established,

the severity of the catastrophe is generated based on a lognormal distribution, and the allocation among states (the focal point state and neighboring states) is determined based on historical patterns. By repeating the process for each catastrophe determined in the first step, the total catastrophe losses by state for a given year are determined. The insurer is then assigned a share of these losses based on its market share in each state. These catastrophe losses are then incorporated into the underwriting module to determine the total loss experience of the insurer.

Another module reflects reinsurance agreements the insurer has in force. These contracts can be on a quota share basis, excess of loss, or catastrophe contracts. The details of the existing contracts are entered into the model, and the loss experience that is generated by the model is applied to those contracts to determine the loss experience, net of reinsurance. Reinsurance premiums and losses are then included in the underwriting experience of the insurer.

The other major source of income for an insurer is investments. The investment module uses stochastic variables to generate interest rates, inflation rates, and equity returns, which then are used to determine the investment income from interest and dividends, and the changes in asset values. The interest rate model used in Dynamo is a one-factor Cox–Ingersoll–Ross (CIR) term structure model. This generates nominal interest rates each month for the next 20 years, so that both short-term and long-term interest rates can be calculated. Inflation rates are determined from a second stochastic equation that reflects the correlation with interest rate levels. Equity returns are modeled on the basis of a separate stochastic model that is based on the expected risk premium adjusted for changes in interest rates, along with a random factor. An increase in interest rates of 100 basis points reduces the expected risk premium by 400 basis points. The one-factor CIR model is a mean reverting square root model, with the strength of the random factor proportional to the square root of interest rates, so negative interest rates do not occur. The one-factor model is sufficient for most property–liability insurance applications, as results are not heavily dependent on interest rate changes. Catastrophe losses and the underwriting cycle play a larger role than interest rates in the financial results for most property–liability insurers. Life insurers and banks tend to use two-factor term structure models, as interest rates and investment returns are the

most significant sources of uncertainty for many of these organizations. Other DFA models use different interest rate models. Some generate real interest rates by a term structure model and inflation separately, and then combine these to obtain nominal interest rates. Equity returns are also modeled in a variety of ways. One alternative method is to incorporate a regime switching model that shifts the parameters of the model for the risk premium based on Markov process, with one regime having a higher expected return and lower volatility and the second regime having a lower expected return and higher volatility.

The investment module generates investment income that reflects the investment allocation of the insurer, between equities and bonds, and the maturity distribution of the bond portfolio. This module also generates the market and statutory values for the assets. This module, combined with the underwriting, catastrophe, and reinsurance modules, produces aggregate operating results for the insurer. The final module incorporates taxation, based on the current tax rates and the investment allocation between taxable and tax-free bonds. When all the modules are combined, the total after tax operating statements and balance sheet for the insurer are calculated for the next 5 years. Each iteration requires over 1000 random variables, and tens of thousands of calculations. Each run of this program will perform hundreds of iterations in order to determine a probability distribution for future financial positions. This type of simulation could not be done prior to the development of powerful computers that perform these operations.

Sample output from a DFA model is shown below. In Figure 1 the year-end statutory surplus of an insurer is shown based on a run of 1000 iterations.

Figure 1 Distribution of year-end surplus

This information would be useful to determine the financial condition of the firm by considering the likelihood that the surplus falls below an acceptable level. In Figure 2, the results of the terminal value of a firm is shown for 500 iterations under different growth rates, ranging from 0 to 10%. Comparison of the distribution of the results can help an insurer determine the optimal growth policy.

Once a DFA model is run, a firm can determine the likelihood of its developing financial difficulties on the basis of its current operating conditions. For each iteration associated with financial difficulties, all the relevant variables can be captured and analyzed. For example, a firm could discover that most of the incidents of financial impairment are associated with unusually large catastrophe losses. This could lead a firm to revise its reinsurance contracts or to change the lines of business it writes, or the geographical areas in which it operates. An insurer may decide to stop writing property coverage in coastal areas based on its DFA model.

Although the results of most DFA applications are proprietary, one published DFA application determined the optimal premium growth rate for an insurer [3]. Rapid growth can impair the value of an insurer, as premium levels may have to be reduced or expenses have to increased to attract significant numbers of new policies. In addition, information asymmetries cause the loss ratio on new business to exceed that on renewal business [4]. Alternatively, low levels of growth do not generate sufficient premium volume to increase the value of the firm. The publicly available DFA model is used to determine the growth rate that optimized firm value.

Figure 2 Firm values under different growth rates

Despite the power of an effective DFA model, care needs to be used in using these models. DFA, as any model, is a simplified representation of reality. Many factors that can influence results are not included in the models in order to focus on the primary factors. Thus, all the uncertainty is not reflected in the model; actual results will vary more widely than the model will indicate. Models are built on the basis of what has happened in the past, not on what new conditions can arise. Firms that do not recognize this inherent uncertainty, and accept levels of leverage that are based on the results of a DFA model, are more exposed to risk than they and their regulators realize. Also, situations can change so that factors not included in the model will become so important that they need to be added in the future. DFA is dynamic in the sense that it will continually evolve. Finally, some factors are simply too difficult to quantify, and therefore are not included in the model. An example would be the chance of management defrauding the firm, which is a significant factor in insurance insolvency, but would be extremely difficult to quantify accurately. What is the likelihood that a firm would be willing to assign to the chance that its management is committing fraud? This value would be quite low in most well run firms. In those more exposed to this risk, it is unlikely that the firm

would recognize or be willing to place a realistic level on this risk as a form of self-denial. In general, DFA can be useful as a guide for firms, but they must be used with a healthy dose of skepticism.

STEPHEN P. D’ARCY

Early Warning Systems (EWSs) for Predicting Financial Crisis

Scientists have been working for decades on early warning systems (EWSs) to predict the occurrence of natural disasters; however, research on the application of EWSs in financial markets has gathered momentum only in the past decade. A commonly known triggering point that aroused such an interest was the financial crisis in Mexico, aka the Tequila crisis, in 1994. Research in this area was given a further boost during the aftermath of the Asian financial crises in 1997/1998. Natural disasters such as tsunami, can cause the loss of thousands of human lives and the financial damage caused cannot be underestimated. During the Asian financial crises, for example, the disruption to economic activities and hence the quality of life of those affected was substantial. This is why there has been such an immense interest in the development of EWSs to predict a financial crisis, so that the government can implement appropriate policies to prevent it, and financial market participants can take proper measures to minimize their losses.

The conceptual framework of EWSs for financial crises is quite simple. It builds on the premise that an economy and its financial markets would behave differently prior to an imminent financial crisis. The “abnormal” behavior has a systematic and recurrent pattern, which is discernible. Therefore, one can judge whether a crisis is about to occur from the movements of relevant economic and financial indicators.

Definition of a Financial Crisis

No EWS will work effectively without a clear definition of what a financial crisis is. Banking crises and currency crises (or exchange rate crises) are generally regarded as financial crises. These crises are not necessarily independent of each other. More often than not, they are interrelated. A banking crisis can easily lead to pressure on exchange rates. Recent research efforts on EWSs have been focusing on currency crises. A possible explanation for this phenomenon is

that banking crises are relatively easier to detect from prudential supervisory information. Banking regulators usually have ready access to financial information and prudential indicators, such as the balance sheet and liquidity ratio of individual banks. In addition, the consequence of a banking crisis is arguably easier to contain with the provision of deposit insurance and lender of last resort by central banks.

To begin with, every EWS requires a quantitative definition of a currency crisis. Currency crises are characterized by abrupt and intensive depreciation pressure, highly volatile interest rate movements, rapid depletion of foreign reserves, or a combination of these phenomena. Abdul Abiad [1] provides a comprehensive survey on how crisis is defined in EWSs. The paper outlines 30 different definitions adopted in recent research studies for a currency crisis. The definitions can be broadly divided into a few groups. First, some EWSs identify currency crises by looking at the extent and speed of depreciation. For example, the Emerging Markets Risk Indicator (EMRI) model developed by Credit Suisse First Boston defines a currency crisis as a depreciation exceeding 5% (or double that of the preceding month) within 1 month.

Another group of models looks at such indicators as exchange rate, interest, and the pace of reserve depletion. The models compare the current value of these variables with their respective value at tranquil periods in order to identify a currency crisis. For example, Kaminsky *et al.* [2] defined a currency crisis as the weighted average of 1-month changes in exchange rates and reserves more than three standard deviations above the country average during tranquil periods. The weighted average is converted into an exchange market pressure index or a speculative pressure index, which takes the form of a binary crisis variable. The index will take the value of 1 if the weighted average exceeds a certain threshold, and 0 otherwise. There are a number of modifications to the approach, such as incorporating “expert judgment” (*see Imprecise Reliability; Expert Judgment; Uncertainty Analysis and Dependence Modeling*) in the construction, focusing only on extreme crises that cause severe economic recession. There are weaknesses in the binary index approach to define a crisis. The main concerns are the loss of information during the transformation of a continuous variable into a binary one. The binary index cannot distinguish between cases with index values below the threshold.

In order to address these concerns, some studies use a continuous index or transform the index into a crisis score within a bounded range.

Choice of Indicators

Like most economic phenomena, financial crisis itself is a concept that is difficult to observe and measure directly. The selection of appropriate indicators is imperative to the success of developing useful EWSs. In general, high-frequency financial market data such as exchange rates and interest rates, provide up-to-date information on a real-time basis but noises are involved. On the other hand, macroeconomic data, such as growth, exports, and capital flows, contain less noise, but are less frequent and only available after a certain degree of time lag. Most studies on EWSs employed both financial market and economic data to construct their models. There are various means to determine the threshold levels for the indicators; see Chan and Wong [3] for choices relating to classification trees. A common and convenient way to do so is to use three standard deviations from the mean value during tranquil periods. Commonly used indicators can be classified into the following three categories.

Macroeconomic Indicator

Macroeconomic indicators are used to measure the robustness of economic activities, degree of external imbalance, adequacy of foreign exchange reserves, and ease of monetary and credit condition. Common indicators under this categories include deviation of exchange rate from trend; current account balance (usually expressed as a ratio of GDP); export growth, ratio of money supply to official foreign exchange reserves; growth of domestic credit and real interest rates.

Capital Flow Indicator

Capital flow indicators measure the degree of lending boom, extent of short-term debt, and composition of capital flows. Common indicators in this category include growth of assets of the banking sector, ratio of short-term external debt to official foreign exchange reserves, amount of portfolio flows, and changes in international investment position.

Financial Market Data

This category of data focuses mainly on the soundness of the banking system. Indicators commonly used are: capital adequacy ratio, loan to deposit ratio, as well as growth in bank deposits and money supply.

Key Modeling Approaches to Early Warning Systems

Since the outbreak of the Asian financial crises in 1997, the International Monetary Fund (IMF) has implemented several models of EWSs to monitor the occurrence of financial crisis. The two most extensive and well-documented approaches are the signal approach and the limited dependent regression approach. These models are outlined below.

The signal approach compares a set of financial market and economic variables, in the period prior to the crises, with their respective values during tranquil periods. A warning signal will be issued whenever there is a large deviation between the extreme values. Under the signal approach, it is necessary to develop objectives and systematic means to identify extreme values (*see Large Insurance Losses Distributions; Extreme Value Theory in Finance; Mathematics of Risk and Reliability: A Select History*) and to decide how many extreme values amongst the set of variables would be needed in order to infer that a crisis may be emerging. The first issue can be addressed by setting the threshold level for each of the variables that gives an optimal balance between the probability of missing a crisis and that of giving out false signals. In practice, this can be done by choosing the thresholds that minimize the noise-to-single ratio. The second issue can be addressed by the construction of an index that takes the weighted average of individual signals.

Kaminsky *et al.* [2] provide a well-documented study on EWSs using the signal approach. The study, commonly known as the (Kaminsky, Lizondo, and Reinhart) *KLR model*, employed data of 20 countries, between 1975 and 1990. Both developing and industrial countries were included in the sample. In the study, a total of 15 economic and financial variables were studied. Values of these variables were compared to their respective levels in a 24-month period prior to the crises in tranquil periods. The study suggested that the top five variables that have

the strongest explanatory power are: (a) deviation of real exchange rate from a deterministic trend; (b) the occurrence of a banking crisis; (c) rate of export growth; (d) equity price movement; and (e) the ratio of money supply (M2) to reserve.

The second approach to EWSs is the use of limited dependent regression models. Similar to the signal approach, this approach generally models the financial crisis as a binary variable, taking a value of either 0 (noncrisis period) or 1 (crisis period). Explanatory variables are selected to undergo a multivariate probit or logit regression (*see Dose-Response Analysis; Credit Scoring via Altman Z-Score; Logistic Regression*) to provide a probability of the occurrence of a crisis within a specific time window. Advocates of this approach argue that it has several advantages over the signal approach. First, it is easy to interpret the model results because the prediction results are always expressed as a simple probability. Secondly, it takes into account the importance of all explanatory variables simultaneously and the usefulness and relevance of any additional explanatory variable can be easily assessed.

Berg *et al.* [4] used the probit model to develop an EWS using the same crisis definition and prediction horizon as the KLR model. The model is commonly known as the *Developing Country Studies Division (DCSD) model*. It is named after the DCSD of the IMF, in which the model was first formulated. The explanatory variables included in the model were deviation of real exchange rate from trend, the ratio of current account balance to GDP, export growth, growth of foreign exchange reserves, and the ratio of short-term debt to foreign exchange reserves.

Mulder *et al.* [5] introduced corporate sector balance sheet variables to the models developed by Berg and Pattillo and found that variables, such as degree of leveraged financing, ratio of short-term debt to working capital, balance sheet indicators of banks, corporate debt to foreign banks as a ratio of exports, and some measures of shareholders rights are useful in the prediction of financial crisis. However, since many corporate sector data are only available once a year and with considerable time lag, this approach may not be able to capture changes in the highly volatile financial markets in a timely manner.

There are many modifications to the limited dependent regression approach. The modifications range from using different geographical coverage,

time periods, and frequency of data and the introduction of new explanatory variables. For example, Weller [6] considered the degree of financial liberalization; Grier and Geier [7] considered exchange rate regime; and Eliasson and Kreuter [8] developed a continuous, rather than a binary measure for financial crisis.

A third approach to EWS is the Markov-switching models (*see Dynamic Financial Analysis; Bayesian Statistics in Quantitative Risk Assessment*). This approach assumes that an economy has two states, namely, tranquil periods and crisis periods. The two states can only be indirectly observed through certain financial market variables, such as exchange rates, that display very distinct behavior in these two states. The approach tries to predict the probability of an economy moving from the tranquil state to the crisis state at a given period of time on the basis of the strength or weakness of an economy's fundamentals. Abdul Abiad [1] developed such a model and found that it correctly predicted two-thirds of crises in sample.

Hawkins and Klau [9] offered another approach to EWSs. Instead of building econometric models to predict financial crisis, they developed the vulnerability indicator approach. They systematically presented various indicators of external and banking sector vulnerability by transforming the value of each indicator into a discrete score within a specific range. An indicator with a higher score suggests greater vulnerability. The scores of individual indicators are summed together with equal weights to achieve an overall vulnerability score that ranges between -10 and 10.

How Well Do Early Warning Systems Work?

To be sure, none of the EWSs developed so far gives overwhelmingly accurate crisis prediction. Crises were missed and false alarms were issued. Berg *et al.* [4] provided a systematic assessment on the effectiveness of a variety of early warning models developed prior to the Asian financial crisis in 1997. In particular, the study found that the KLR model gave fairly good forecasts. Many of the hardest hit economies during 1997/1998, such as Korea and Thailand were successfully identified by the model, although economies that were not so badly hit also appeared at the top of the prediction. The study

concluded that the model was statistically significant and informatively superior to random guessing.

Berg *et al.* [10] revisited the issue and compared the predictive power of the KLR and DCSD models with various nonmodel-based indicators, such as yield spreads and agency rating, between January 1999 and December 2000. The forecasts of the models in question were all “out-of-sample” forecasts. The results of the study were mixed. While the KLR model provided good out-of-sample prediction during the period, the accuracy of the out-of-sample forecast produced by the DCSD model deteriorated noticeably compared with that during the in-sample period. One possible explanation for the mixed results is that the occurrence of financial crises has been limited to a few cases. For example, during the period under assessment, there were only 8 crises out of a sample of over 500 observations. Despite the findings, Berg concluded that EWSs do provide a systematic, consistent, and unbiased means to process and analyze information pertinent to financial crises. While EWSs are not sufficiently robust to be relied upon as the sole tool to predict financial crises, the study affirmed that the best EWSs performed substantially better than non-model-based forecasts over the Asian financial crisis period.

Alternative Approaches to Early Warning System

Given the limitation to the predictive power of EWSs, there are other new frameworks developed to supplement such systems. One of these is the resilient framework that measures the resilience level of an economy. The framework does not attempt to predict financial crisis. It is an assessment of the soundness of economic and financial systems at a particular point of time. Chan and Wong [3] developed such a framework using a two-stage data feedback data mining approach involving the combination of a fuzzy logic framework (*see Imprecise Reliability; Expert Elicitation for Risk Assessment*) and the classification and regression tree (CART) technique to allow users to examine the resilience level of an economy. In their study, economies are classified into five different resilient levels between 1 and 5. The fuzzy logic framework evaluates expert opinions on a set of economic and financial market variables that are similar to those employed in other EWSs, and generates a

fuzzy logic score (from 1 to 5) for each observation. The CART technique then generates decision trees to maximize the likelihood that observations were classified into groups that were originally assigned by the fuzzy scoring system. The end product of the CART process is a decision tree that can be used to generate resilience scores for future observations. Back testing of the resilience framework suggested that it successfully detects substantial deterioration of resilience level of crisis-hit economies.

Conclusion

EWSs provide systematic and objective analyses of macroeconomic and financial market data in predicting financial crisis. This paper reviewed various approaches to the modeling of EWSs for financial crisis and discussed the effectiveness of these systems. Notwithstanding the research efforts and the noticeable progress in this area, there is still yet a sufficiently robust EWS that can be relied upon as the sole system for crisis prediction. Development in other research frameworks that are complementary to EWS such as the resilience framework, is encouraging.

Ecological Risk Assessment

Ecological risk assessment (ERA) is a generic term used to describe any formal process whereby ecological threats are identified, their likelihood of occurrence estimated or guessed, and their consequences articulated. ERA is a subset of environmental risk assessment (*see* **Environmental Hazard; Environmental Health Risk; Environmental Risks**). It focuses specifically on the elicitation, quantification, communication, and management of risks to the *biotic* environment. While environmental risk assessment dates back to the 1930s [1], ERA is relatively new and commenced as a United States Environmental Protection Agency (USEPA) project in the 1980s to develop tools for environmental regulation and management [2]. Since that time there have been rapid advances in the sophistication and complexity of ERA “tools” although, as noted by Kookana *et al.* [3], ERA currently suffers from a poor understanding of processes governing ecological risks and a paucity of appropriate data. Other challenges exist as well, including the following:

- difficulties in identifying pathways for chemicals in the environment;
- lack of understanding of fate and effect of pollutants in the receiving environment;
- high levels of uncertainty in models and processes underpinning the ERA process;
- unquantified errors in model outputs;
- no agreed approach to combining uncertainties of different kinds comprehensively in a single analysis;
- lack of standard approaches to ERA;
- difficulty in developing and applying a “system-wide” ERA – that is quantifying the overall risk associated with multiple stressors and threats;
- diffuse linkages between the outcomes of an ERA and management responses;
- difficulties in assessing the utility of an individual ERA.

With respect to the last point, Suter [2] notes that “assessors have developed methods for determining the likelihood that a safe exposure level will be

exceeded, but have seldom specified the benefits of avoiding that exceedence”. Thus, a certain degree of “evaluation bias” tends to characterize ERAs where the risk of an undesirable ecological outcome is rarely evaluated against the benefit of a desirable ecological outcome. In many instances, the framing and the contextual setting of the problem at hand influence the outcomes of the ERA [4]. To a large extent, they determine the set of solutions considered, as well as the focus of the assessment, the kinds of endpoints used, the time frames considered, the data collected, and who is considered to be a “stakeholder”.

Components of an Ecological Risk Assessment

As with environmental risk assessment, ERAs have been dogged with multiple definitions of risk (*see* **Absolute Risk Reduction**), a confused lexicon, and a lack of a transparent and consistent framework to guide the ERA process [5]. Most environmental decisions are set in socially charged contexts. People stand to gain or lose substantially. Arguments are clouded by linguistic ambiguity, vagueness, and underspecificity to which analysts themselves are susceptible. Prejudice gets in the way of constructive discussion. A transparent framework helps to relieve these impediments.

We use “risk” here to denote the chance, within a prescribed time frame, of an adverse event with specific (usually negative) consequences. Other terms commonly used in ERAs are hazard and stressor. A *hazard* (*see* **Hazard and Hazard Ratio**) is a situation or event that could lead to harm [6]. Ecological hazards can be natural (e.g., cyclones, earthquakes, fires) or related to human activities (e.g., destruction of a habitat). Hazards are possibilities, without probabilities. They are all those things that might happen, without saying how likely they are to happen [4]. Stressors are the elements of the system that precipitate an unwanted outcome (for example, low dissolved oxygen in a river is a stressor that ultimately results in the death of aquatic life). Suter [7] created a system of thinking to help people to define environmental hazards and their consequences. He defined endpoints as an expression of the values that we want to protect. There are three broad kinds:

1. *Management goals* are statements that embody broad objectives, things such as clean water or a healthy ecosystem. They are defined in terms of goals that are both ambiguous and vague but they carry with them a clear social mandate.
2. *Assessment endpoints* translate the management goals into a conceptual model, and satisfy social objectives. Clean water may be water that can be consumed and bathed in by people. A healthy ecosystem may be one in which all ecological stages are represented, all natural ecological processes continue to operate, and populations of important plants and animals persist. But assessment endpoints cannot be measured.
3. *Measurement endpoints* are things that we can actually measure. They are operational definitions of assessment endpoints that are in turn, conceptual representations of management goals. Thus, measurement endpoints for freshwater may include counts of *Escherichia coli* or the concentration of salt. Measurement endpoints of a healthy ecosystem may be the abundance of several important species (threatened species or game species), and the prevalence of diseases and invasive species.

We have defined risk to be the chance or likelihood of an adverse outcome. Probability is a mathematical construct (a metric) that quantifies the likelihood of uncertain events. In this context, the duality between risk and probability is apparent and these terms are often used interchangeably in ERAs. The “frequentist” definition of probability is based on the statistical frequency (or relative frequency) with which an event is expected to occur. The term *subjective probability* also has two meanings. The first meaning is a lack of knowledge about a process or bias. The second meaning is that it indicates purely personal degrees of belief. Personal beliefs are unknown only insofar as a person does not know his/her own mind [8] (see **Bayes’ Theorem and Updating of Belief; Bayesian Statistics in Quantitative Risk Assessment**).

Standard approaches to risk analysis (see **Volatility Modeling**) may be particularly vulnerable to psychological frailties including insensitivity to sample size, overconfidence, judgment bias, anchoring (the tendency to provide subjective assessments similar to those already proposed, or proposed by a

dominant individual in a group), and arbitrary risk tolerance (see reviews by Fischhoff [9], Morgan *et al.* [10], and Freudenburg *et al.* [11]). In addition, scientific training fails to acknowledge the pervasive presence and role of linguistic uncertainty [12], particularly the vague, underspecified, and ambiguous language that characterizes many risk assessments.

Challenges for Ecological Risk Assessment

It is challenging to consider the full extent of uncertainty present in any analysis, to characterize it fully and carry the uncertainties through chains of calculations and logic. A host of new methods offer prospects for solutions; in addition to standard treatments such as probability trees (see **Decision Trees**) and *Monte Carlo*, emerging approaches include fuzzy numbers, rough sets, evidence theory, imprecise probabilities, probability bounds, game theory, and *decision analysis* (see **Decision Analysis**). The task lies ahead to evaluate these methods and develop experience in their use so that they can be applied effectively and routinely.

Adams [13] argued that risk assessments always involve decisions about values and preferences, and are colored by the personal experiences and prospects of the individuals conducting the assessments. He argued that, in general, we get by with crude abstractions shaped by belief. This view objects to the artificial separation of stakeholder, risk analyst, and manager/decision maker [14]. Instead of using technical analysis, risk assessments could be conducted through stakeholder engagement, elicitation of preferences and values, and consensus building. Adams may be right. Certainly, the importance of psychology and context provide strong support. The answers generated by quantitative risk analysts may be little more than smoke and mirrors, reflecting the personal prejudices and stakes of those conducting the analysis. It is likely that at least some of the problems alluded to by Adams will affect all risk analyses. The extent to which they are felt will depend on the nature of the problem, the amount and quality of data and understanding, the personal outcomes for those involved in the analysis, and the degree to which their predispositions can be made apparent.

Many disagreements among stakeholders are resolved by seeing clearly what the other participants want, and why they want it. Risk assessments that

combine social preferences with formal analytical tools can have their greatest utility in meeting these challenges. They work when they are logically robust and relatively free from linguistic ambiguity. They are not necessarily any closer to the truth than purely subjective evaluations. But they have the potential, if properly managed, to communicate all the dimensions of an ecological problem to all participants. They may do so in a way that is internally consistent and transparent, serving the needs of communication (assuming appropriate skills in the analyst).

ERA is relatively new and as such is still “finding its feet”. While it is acknowledged that more work needs to be done in harmonizing different quantitative approaches, developing a consistent lexicon, and producing robust guidelines, natural resource managers and environmental stakeholders have much to gain from the formalized approach to environmental decision making under uncertainty.

Economic Criteria for Setting Environmental Standards

The development and choice of standards or guidelines to protect the environment and human health from pollution and other hazards can be achieved by directly controlling emissions of pollutants, by allowing some economic optimization based on legal standards, or a combination of both. As always, the justification for a choice of control system depends on the regulatory context. That is, specific statutes will direct an agency to perform some type of economic analysis, but not permit another to justify its choice of technology and then impose it on the producers of the hazard. For example, a statute may explicitly ask that a standard be set on the balancing of the risk, costs, and benefit; another may limit those analyses to risks only.

Economic costs include the value of all impacts that can be stated in monetary units, that is, these factors are *monetized*. However, some costs and benefits cannot easily be monetized because they are intangible, or not priced by the market, directly or indirectly. For example, the value of improving visibility by reducing air pollution (*see* **Air Pollution Risk**) is an environmental service not generally priced by the market, unlike the value of reductions in morbidity or mortality from the same type of pollution. Nonetheless, economic methods can be used to approximate those intangible costs (e.g., *via* methods such as hedonic pricing) so that the price paid by the consumer correctly *internalizes* (incorporates) all costs, for given levels of social benefit, resulting from a reduction in pollution.

As always, regulatory laws must consider economics as well as the full aspect of regulation: statutes, secondary legislation, and judicial review *via* case law. In the United States, costs have been found by the courts to be important, but not likely to limit the use of expensive technology, unless those costs were disproportionate to the benefits achieved by the selected control technology. The US Federal Water Pollution Control Act imposes a limited form of cost-benefit analysis (CBA) for water pollution control (*see* **Water Pollution Risk**) depending on the level of effluent control (33 U.S.C. Section 1251

et seq.). Marginal cost (the cost per unit of mass of pollution removed) analysis of control technology plays an important role in determining the level of effluent discharge permitted. The case *Chemical Manufacturers Association v. EPA* (870 F.2d 177 (5th Cir. 1989)), which dealt with changes in the marginal cost of controlling effluent discharges, exemplifies how cost-effectiveness can be used in risk-based regulations. The US EPA can impose a standard, unless the reduction in effluent is *wholly out of proportion* to the cost of achieving it. In the US case *Portland Cement Assoc. v. Ruckelshaus*, the court held that Section 111 of the Clean Air Act (CAA) explicitly requires taking into consideration the *cost of achieving emission reductions* with the *nonair quality health and environmental impacts and energy requirements* (486 F.2d 375, cert. den'd, 417 U.S. 921 (1973)). The court then found that the US EPA met the statutorily required consideration of the cost of its regulatory acts (*Sierra Club v. Costle*, 657 F.2d 298 (D. C. Cir. 1981) explains these issues).

We focus on three conceptually different ways to balance the cost and benefits associated with risky choices:

- *cost-effectiveness analysis* (CEA) and methods such as ALARA (as low as reasonably achievable) and ALARP (as low as reasonably practicable);
- *cost-benefit analysis*, CBA;
- *legal feasibility analysis*.

Cost-Effectiveness

A concern of CEA is the efficiency of removal of pollution (measured by appropriate physical units, such as micrograms of particles per cubic meter of air, $\mu\text{g m}^{-3}$) of alternative pollution control technologies that are added to physical facilities such as power plants, to maximize the reduction in the emissions of pollutants. A narrow view of economic efficiency – specific to pollution removal – drives this form of balancing. It consists of calculating the efficiency (in percentage) in pollution removal, capital costs, and variable costs such as those associated with operation and maintenance, for alternative pollution control technologies designed to achieve the same technical objective (such as removing a specific quantity of particulate matter, solids, from a process).

CEA is also used to study the economic gains made by substituting fuels that have a higher content of pollutants by those having a lower content (e.g., high versus low sulfur fuel oil). For example, the European Union (EU) REACH Program looks at the reductions in risk (the focus of Regulation, Evaluation and Authorisation of Chemicals (REACH)) on a per chemical basis with changes in cost because of changes at the manufacturing level. CEA can also be coupled to life cycle, and cradle-to-grave risk analysis. Specifically, CEA can be a basis for setting exposure limit values (e.g., in the EU Directive 2004/40/EC); these are as follows:

limits on exposure to electromagnetic fields which are based directly on established health effects and biological considerations ... that will ensure that workers exposed ... are protected against all known (short-term) adverse health effects.

The reduction in risk should be based on the general principle of prevention (Directive 89/391/EC).

In many risk assessments, the alternative choices of environmental control technologies to reduce pollution, and thus reduce risk, can be represented as depicted in Figure 1. Note that the efficiency of pollution removal falls between 0 and 100%. Figure 1 depicts three hypothetical technologies that can be used to reduce the emission of pollutants; each technology is not divisible and is mutually exclusive to the other. This economic evaluation is limited to engineering factors, such as thermodynamic efficiency, derating owing to use of energy for operating the pollution control technology (if the technology were not used more energy would be available for sale to the consumer), and so on. The change in the cost of a technological choice can be understood as follows. The change (generally,

Figure 1 Three hypothetical, not divisible alternative environmental pollution control technologies

an increase) in capital and operating costs in going from the *best practicable control technology* (Technology A) to the *best available control technology* (Technology C), which may involve an intermediate technology, the *best conventional control technology* (Technology B), produces social benefits by reducing adverse outcomes or risk (however measured, possibly as number of deaths or any other factor for the various outcomes) by being more efficient in reducing the emission of pollutants.

Risk assessment yields an evaluation of the probability and magnitude of the consequences from exposure to one or more hazards and their severity. Severity of the consequences suggests that length of stay in hospital or at home from an injury or a disease, permanent damage, or death are some of the attributes that should be considered in measuring it. Accounting for severity results in an indicator composed of two components. The first is the number of life years lost (LYL), calculated by addition, over all relevant health endpoints, of the product of the number of deaths caused by a specific disease and life expectancy, at the age of death because of that disease EC [1]. The second is the years lived with disability (YLD), which is the sum of the product of the number of persons affected by a nonlethal disease, the duration of this disease, and a weight to account for its severity. The disability adjusted life years (DALY) is the summation of LYL and YLD. For example, the United Kingdom, UK, Treasury guidance on CEA [2], states that:

Cost-effectiveness analysis compares the costs of alternative ways of producing the same or similar outputs. One relevant form of CEA uses the “quality adjusted life year (QALY)” output measure.

The QALYs, according to the HM Treasury [2]

are estimated by assigning every life-year a weight on a scale where one represents full health and zero represents death. The most common methods of determining the health related utility values to weight QALYs are:

- the standard gamble: an individual is asked to consider two alternatives, full health, with a risk of death, and an imperfect state of health, with no risk of death;
- the time trade off: an individual is asked to consider how many years in full health would be equivalent to, say, five years in a given health state;
- the visual analogue scale: a thermometer type scale where full health is shown at the highest

point, and worst possible health state is shown at the lowest point. Individuals simply indicate where on the scale they feel that the health state is located; and,

- the person trade-off: individuals are asked what number of people being cured from one particular state is equal to, say, ten people being saved from death.

To clarify, we provide two of the examples developed by the UK HM Treasury [2] using QALYs and the *EQ-5D* (European Quality of Life 5 Dimensions) scale.

Example 1 Scores for the EQ-5D are given across 5 different dimensions: mobility; pain/discomfort; self-care; anxiety/depression; and the ability to carry out usual activities such as work, study, housework, and leisure pursuits. Each of these is scored out of 3 alternatives (e.g., for mobility – no problems; some problems walking about; confined to bed), giving a total possible combination of 243 health states (in addition, unconsciousness and death are included). Using the techniques above, patients are asked to self-score their health state and their views about their state of health relative to normal health (a score of 1) and death (a score of 0). Some examples of the health states (and their QALY values in brackets) are as follows:

- 11111 – no problems (QALY in such a state: value = 1.0);
- 11221 – no problems walking about; no problems with self-care; some problems with performing usual activities; moderate pain or discomfort; moderately anxious or depressed (0.760);
- 12321 – no problems walking about; some problems washing or dressing self; unable to perform usual activities; some pain or discomfort; not anxious or depressed (0.516).

Example 2 A safety measure might prevent approximately 100 people per year from suffering an average loss of 5 QALYs each, from chronic health effects. Thus: QALYs gained = $100 \times 5 = 500$ person-QALY/year. Using current benchmarks for QALYs at 18, an acceptable maximum cost of preventing this loss is $500 \times £30\,000 = £1.5$ million. Alternatively, this resource might be spent to prevent a single expected fatality per year, as it is close to the upper benchmark.

As Low as Reasonably Achievable, ALARA, or Practicable, ALARP

These specialized approaches relate economic cost to reductions in exposure either in occupational or

environmental settings. For example, the ALARA analysis “should be used in determining whether the use of respiratory protection is advisable” (US Nuclear Regulatory Commission [3]). The US Department of Energy (DOE), also bases some of their policies and procedures for safely dealing with exposure to ionizing radiation on ALARA (10 CFR 835.101). The ALARA principle is based on the (in some instances, assumed) proportionality between the cost and the effectiveness of safety measures being studied – costs are incurred to decrease the risk, given the alternatives being studied. Specifically, an ALARA for radioactive substances is \$1000/person-rem *averted*, which is taken to be the limit of cost-effective reduction in radiological exposure for the public [4]. It is *an upper limit on an individual’s permissible radiation dose*; here, *reasonably achievable* means *to the extent practicable* [3]. Importantly, there is no requirement that *radiation exposure must be kept to an absolute minimum*. Thus, the driving force is the combination of practicability of safety, which is a function of *the purpose of the job, the state of technology, the cost of averting dose, and the benefits* [3].

The United Kingdom has health and safety legislation requiring that risks be reduced “as low as is reasonably practicable” (ALARP). The

legal interpretation ... is that a risk reduction measure should be implemented, unless there is a ‘gross disproportion’ between the cost of a control measure and the benefits of the risk reduction that will be achieved.

In the United Kingdom, a legal definition of *ALARP* is given in *Edwards v National Coal Board* (1949):

‘Reasonably practicable’ is a narrower term than ‘physically possible’ ... a computation must be made by the owner in which the quantum of risk is placed on one scale and the sacrifice involved in the measures necessary for averting the risk (whether in money, time or trouble) is placed on the other, and that, if it be shown that there is a gross disproportion between them – the risk being insignificant in relation to the sacrifice – the defendants discharge the onus on them.

The ALARP ensures that the exposure of workers and the general public to risk is *as low as reasonably practicable*. One framework (below) has been devised to interpret this requirement [2]:

Furthermore, this test of reasonableness applies to all risk levels, although in practice regulators may develop decision boundaries, as Table 1 shows.

The EU has *proportionality* as one of its main guiding principles. This principle has affected UK and European laws by setting out a number of criteria for CEA: ALARA, BPM (best practicable means), BPEO (best practicable environmental option), and BAT (best available techniques). Each of these has its own characteristics, but all are based on the trade-off between risk and the cost of reducing it [2].

Viscusi [5] exemplifies ways in which a cost-effectiveness assessment can put into perspective government interventions using a common metric – the costs of saving lives. An abstract of these numbers (in 1984, \$US) is given in Table 2.

The National Highways Traffic Safety Administration (NHTSA), and the Occupational Safety and Health Administration (OSHA), save statistical lives at the costs depicted in Table 2. The range of *costs per life saved* between mandating passive restraints and formaldehyde exposure in the workplace is approximately \$72 000 million. Abelson

[6] summarized the cost of regulating pollution as approximately averaging \$115 billion (in \$1990). Using 1984 dollars means that all values expressed in dollars are transformed into constant 1984 dollars. 1984 is the *base-year*. Values in dollars in other periods, say 1986, are *nominal*. This transformation uses an index such as the *price index*.

Because CEA does not include all of the positive and negative social impacts of a technological choice, it is limited in scope, as Figure 1 depicts in terms of three hypothetical technologies and Figure 2 depicts in terms of a smooth cost function. To overcome this limitation, and to account for change in the social costs because of diverting societal-scarce resources while reducing risks, it is preferable to use CBA fully to assess the effect of changes in reducing the burden of pollution. The net result – addressed by CBA – involves the assessment of the damage from pollution balanced against the tangible and intangible costs to society because of that reduction, possibly accounting for uncertainty. Clearly, there is a trade-off in going from CEA to CBA – more costs and more time consuming, with the possible introduction of spurious relationships.

Table 1 Relationships between tolerability of risks and criterion for action

Category	Action required	Criteria
Intolerable	Extremely reluctant to accept any arguments for not doing more to reduce the risk	If for workers, a risk of death of 1 in 1000 per annum
Tolerable if as low as reasonably practicable	A case specific “ALARP” demonstration is required. The extent of demonstration should be proportionate to the level of risk	Risk levels broadly between “intolerable” and “broadly acceptable”
Broadly acceptable	No case specific demonstration is required. The “ALARP” demonstration should be fairly straightforward, assuming existing codes of practice etc. are up to date	For workers and the general public, if it is a risk of death of 1 in 1 000 000 per annum

Table 2 Selected cost per life saved (millions 1984 \$US, Viscusi, 1993) by technological choice^(a)

Action	Agency, year of regulation	Annual risk	Expected number of annual lives saved by regulation	Cost per life saved (millions 1984 \$)
Passive restraints/belts	NHTSA, 1984	9.1×10^{-5}	1850	0.30
Occupational benzene exposure	OSHA, 1987	8.8×10^{-4}	3.8	17.10
Occupational formaldehyde exposure	OSHA, 1987	6.8×10^{-4}	0.01	72000

Figure 2 Hypothetical marginal cost function

Cost-Benefit Analysis (CBA)

CBA is the complete economic analysis of the impact of a standard (*see Cost-Effectiveness Analysis*). It thus subsumes risk analysis in the sense that risks – a form of social costs – are one of the many costs that society incurs when benefiting from development. CBA benefits from a number of economic subdisciplines that include microeconomics, public finance, financial management, welfare, labor, and environmental economics. Simply put, it is summarized by calculating the present discounted value (PDV), of the difference between the total *social* costs and the total *social* benefits of one or more actions, discounted at the appropriate social discount (or interest) rate. Each action has the same objective. The final choice of the best options is guided by the maximization of the net discounted benefits or by the minimization of the net social costs. A deterministic expression for CBA is derived from the formula for the future simple discounted value of an amount of money, A , which is held today, calculated for t uniform periods of time at a (constant) interest rate r (dimensionless) is given by

$$\text{Future Compounded Value, } FCV = A(1 + r)^t \quad (1)$$

The PDV is (A is changed to $(B_t - C_t)$) given by

$$PDV = \sum_t (B_t - C_t) / (1 + r)^t \quad (2)$$

The PDV formula provides today's ($t = 0$) monetary value of a discrete stream of net benefits, calculated as the difference between costs C , and benefits B , discounted at a rate r , over a number of periods of time (symbolized by $t, t = 1, t = 2, \dots$), beginning at time $t = 0$. If a single, lump sum value (a single

sum without prior payments) of the net benefits were sought, the formula simplifies to

$$PDV = [(B_t - C_t) / (1 + r)^t] \quad (3)$$

Example 3 Let the value of the benefit equal \$10 000.00 and the cost equal \$5 000.00, the number of yearly time periods is 10. Assume a constant interest rate of 5%. Today's value of the net benefit that will be generated only at the end of year 10 is $PDV = 5000 / (1 + 0.05)^{10} = \3069.57 . In this calculation the interest rate is *nominal*, which means that inflation and the risk of default is included in the 5%. The *real* interest rate might be about 2%.

The formula for rank-ordering potential actions through the CBA is as helpful as it can be deceptive, because of the way certain components in the formula can be manipulated to emphasize its results. Although most formulae can be manipulated, a clear vulnerability exists in that many environmental intangibles can only be approximated because they fall outside the more precise operations of the market. A second aspect concerns the choice of the discount rate. The decision rule is to choose the alternative that yields the largest positive PDV. The formula is not sensitive to monetary unit – using the Euro, dollar or pound does not affect the rank order of a choice. However, the choice of the base year for the monetary unit (e.g., 1980 \$ rather than current \$) can affect the rank order of the alternatives. Therefore, a constant dollar should be used in the calculations. A net *disbenefit* occurs when the difference between the costs and benefits is negative. If compounding occurred more frequently within a year, for example quarterly, the formula would have to be changed slightly to reflect that situation.

Example 4 The cumulated discounted value of an initial amount $(B - C)$, in which the interest rate per year is r , and k is the frequency of compounding per year for n years. A sum can be compounded k/r times per year as follows: $(\text{initial amount}) \times [(1 + r/k)^k]^n$. Consider the simple interest payments for \$1000 for 2 years at 10% per year: $1000(1 + 0.10)^2 = \$1210$. The effect of compounding interest four times over 2 years yields \$1216: $1000(1 + 0.05)^4 = \$1216.00$.

The process for obtaining a CBA can be summarized as a sequence of key steps (nothing

is said about the political viability of the preferred alternative):

Define the Objective → Identify Mutually Exhaustive and Complete Set of Alternatives (Options or Actions) to Reach that Objective → For Each Alternative, Measure Social Risk, Costs and Benefits → Calculate the Net Present Discounted Value (using the same discount rate) of Each Alternative → Rank Each Alternative According to the Magnitude of Its Net Present Discounted Value (if the technologies are divisible, the ranking can be based on the benefit to cost ratio (B/C)) → Performing Uncertainty Analysis to Assess the Dominance of the Preferred Alternative, Relative to other Alternatives → Recommend to Decision-Makers (and stakeholders) the Choice of the Preferred Option, Basing such Choice on the Maximum Net Present Discounted Value (or the B/C ratio with the highest value, when the projects are divisible).

Discounting occurs over the economic lifetime of the alternatives considered; it is the means to account for the effect of time on the value of money. The alternative yielding the highest positive difference ($B - C$) is optimal. The calculations include direct costs and benefits, such as employment and employment effects, as well as indirect costs and benefits, whether tangible or not. This type of analysis also includes anticompetitive effects, if the alternatives being studied cause such effects. Hence, distortions to the labor market, price-induced effects on wages, and so on, are part of CBA, if relevant to the specific application. For example, the US National Environmental Policy Act (NEPA, 42 U.S.C. Sections 431–4347), one of the earliest modern environmental protection acts (enacted in 1972), requires the balancing of the environmental costs of a project against its economic and environmental benefits. Although a numerical balancing is often involved, NEPA does not require the calculation of a numerical cost-benefit ratio or the computation of the net cost-benefit number for each alternative taken to mitigate an environmental impact. It should come as no surprise that CBA has generated many disputes between stakeholders such as environmental organizations, industry, and the US EPA.

A recent case exemplifies the issues. In 2001, the US Supreme Court affirmed that, under Section 109 of the CAA (amended, 42 U.S.C. Section 7409(a)), federal standard setting (for the National Ambient

Air Quality Standards (NAAQS)) for particulate matter and tropospheric ozone must be set *without* consideration of costs and benefits. The new ozone NAAQS was being lowered to 0.08 ppm, and for the first time the EPA was regulating 2.5 μm particulate matter (lowered from 10 μm). The sources of particulate matter being regulated were principally trucks and other diesel engines, and mining. The rationale for lowering the particulate matter standard was that it would reduce the number of premature deaths by 15 000 per year and serious respiratory problems in children by 250 000 per year. According to the US Chamber of Commerce, to implement these regulations it would cost industry approximately 46 billion US dollars per year. This case, decided by the US Supreme Court as *Whitman, Admin. of EPA, et al. v American Trucking Associations, Inc., et al.* (No. 99–1257, February 27, 2000) addresses four issues, two of which are critical to understanding setting of ambient environmental standards under Section 109(d)(1). This legislative mandate is the *attainment and maintenance ... requisite to protect the public health with an adequate margin of safety*. It is explicit. The Supreme Court held that *section 109(b) does not permit the Administrator to consider implementation costs in setting NAAQS*. *Whitman* stands for the proposition that the requirement by Congress must be clearly stated – if costs and benefits are considered, the CAA must specifically allow it. If it does not, it is most likely an agency cannot supplant what the Congress did not wish.

The legislative *adequate margin of safety* does not trigger CBA by itself. It only commands the Administrator of the EPA to adopt an unspecified degree of conservatism, as can be represented and achieved using factors of safety (numbers between 1 and 10, multiplied, and then applied to scale down the exposure to make it smaller and thus, in principle safer, for those at risk). However, not all sections of the CAA, are so stringent as to the level of conservatism (errring on the side of safety, when there are remarkable scientific uncertainties, as was held in *Union Electric Co., v EPA*, a US Supreme Court decision (427 U.S. 246 (1976))). This case illustrates the issue of having to consider economic factors (e.g., costs of compliance) when attempting to safeguard human health. Specifically, costs *are* excluded under Section 109, the section governing NAAQS, but risks are not (established by Congress under Section 109(b)(1)); as held in *Lead Industries Assoc., v EPA* decided

in a lower court (647 F.2d 1130, 1148 (CA DC, 1980). Even though the CAA seems to be very clear, nonetheless, the issue of costs was litigated all the way up to the US Supreme Court: the *Whitman* decision appears to settle this issue – the clear absence of a command to account for costs was not an omission by Congress. Section 109 is protective of human health and welfare. The American Trucking Association argued that imposing stringent air pollution standards would increase the risk to health by increasing unemployment because industry would have to lay off workers. The residual risks can be the increased number of suicides, violence at home, and other social problems such as those caused by unemployment. After reviewing the record from the early days of the CAA, from 1967 to February 27, 2001, the Court determined that Congress was quite explicit when it *wanted* to include any consideration of cost. It had done so in other cases involving water and air pollution. With regard to Section 109, the Court found that Congress (*Senate Report* No. 91–1196, pp. 2–3 (1970)) clearly meant to be protective and thus was only concerned with risks.

The health of the people is more important than the question of whether the early achievement of ambient air quality standards protective of health is technically feasible. ... (Thus) existing sources of pollutants either should meet the standard of the law or be closed down ...

The Supreme Court rejected the American Trucking Association's contention that the phrase *adequate margin of safety* does not provide an *intelligible principle* of protection, therefore being vague and thus unconstitutional. The CAA requirement is that the EPA must establish that

(for the relatively few pollutants regulated under Sect. 108) uniform national standards at a level that is requisite to protect public health from the adverse effects of pollutants in the ambient air.

The term *requisite* legally means *sufficient, but not lower or higher than necessary*. This is a key constitutional constraint that bounds the US EPA's ability to set standards: if it is exceeded, then the EPA has violated the Constitution because it now has *legislated* change. The Court held that Section 109(b)(1) of the CAA does not grant the US EPA legislative powers: an agency cannot use its own interpretative discretion to somehow gain what it cannot have. Moreover, the US EPA cannot arbitrarily construe

statutory language to nullify *textually applicable provisions* (of a statute) *to limit its discretion*. The US Constitution prohibits the Executive branch of the government from legislating. Legislation is the prerogative of the Congress of the United States. Justice Breyer agreed that the CAA is unambiguous on this point: costs are not included in the determination of the NAAQS. He concluded that *a rule likely to cause more harm to health than it prevents is not a rule that is requisite to protect human health*. Section 109(a) does not preclude comparative risk assessments. An even more complex analysis extends the domain of CBA to include industry-wide effects: it was used by the US Supreme Court in a case concerned with occupational exposure to airborne benzene (a carcinogen, discussed in the next section).

Legal Feasibility Analysis

Legal feasibility analysis should not be confused with the more traditional feasibility analysis that is an initial stage in the investigation of the feasibility of a project and thus entails a bounding of costs before a more comprehensive engineering analysis is undertaken. *Feasibility analysis*, in the present context, determines the extent to which some firms in an industry can fail, when that industry, as a whole, is not threatened. The phrase *to the extent feasible* was held to mean *capable of being done* by the US Supreme Court, when it found that Congress had carried out the appropriate cost-benefit balancing. This fact excluded an agency of the government from doing such balancing, particularly when Congress intended to place *the benefit of the workers' health above all other considerations, save those making the attainment of the benefit unachievable* (*American Textile Manufacturers Assoc. v Donovan, U. S. L. Week* 49: 4720 (1981)). The federal agency involved in this dispute was the federal OSHA, which had estimated the cost of compliance with the new standard, determined that such costs would not seriously burden the textile industry and would maintain *long-term profitability and competitiveness* of the industry [7]. The relevant section of the Occupational Health and Safety Act (29 U.S.C. Sections 655(b) </(5) and 652(8)), states as follows:

The Secretary ... shall set the standard which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no

employee will suffer material impairment of health or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life.

Although not called *feasibility analysis*, there are parallels to this line of legal reasoning in the EU, where an important limitation to regulations is illustrated by the annulment of the EU's first comprehensive ban on direct and indirect tobacco advertising and sponsorship (*via* Directive 98/43/EC) by the European Court of Justice (ECJ) in 2000, in a case that saw the German Government and four British tobacco companies sue the European Commission. The judgment by the Court held that the Directive 98/43/EC was disproportionate to its means, principally because it did not harmonize competition but tended to destroy it. The restrictions the Directive placed on trade in tobacco were seen as disproportionate to those needed to ensure the proper functioning of the internal EU market [8].

Bubble, Trading of Emissions, and Other Instruments

Traditionally, environmental pollution standards are imposed by law and are monitored according to specific protocols that are also legally enacted and enforced. This form of environmental protection has been called *command and control*. Typically, an environmental statute sets principles, legal tests, and other forms of guidance that are then used by a regulatory agency, or an authority of the government, to set pollution standards. Standards are then set through those regulations (secondary legislation) uniformly for a country or region, unless there are specific regional requirements that result in special standards for that region. Although this is a simplification, as those familiar with special provisions of the law for state implementation plans know, it is a basis for command and control regulatory standard setting. An example is the US National Primary (protecting human health) and Secondary (protecting other welfare aspects such as visibility, vegetation, and so on) Air Quality Standards for sulfur dioxide, particulate matter, carbon monoxide, ozone, nitrogen dioxide, and lead that were promulgated, under authority of the CAA, by the US EPA. These standards apply to specific *stationary* sources of pollution, such as fossil-fuels burning power plants; they are numerical

and include suitable averaging times, (e.g., for SO₂, the US federal primary standard is 80 µg m⁻³ of air, annual arithmetic mean). The standards have been set at the level appropriate to protect sensitive individuals and not just the average member of the US population. Primary Standards were set without the CAA explicitly demanding that the US EPA should account for the costs of regulation before issuing the standards. Command and control regulatory framework is often associated with forcing new pollution technology, such as *the best available control technology* to achieve requisite level of emissions. Achieving the concentration of pollutants set forth in those standards has resulted in complex relations between the states and the federal government. These, in turn, have resulted in the creation of *State Implementation Plans, New Source Performance Standards, Prevention of Significant Deterioration, Lowest Achievable Emission Rates, Reasonably Available Control Technology*, and others [9].

Legislators have come to realize that profits are either preferable to command and control regulatory standards alone or can help minimize costs by using economic instruments in a portfolio of options for the producers of pollution. For example, the US EPA has been working with economic incentives, such as the offset program, since the 1970s. The *offset program* requires that a new stationary source operating in a region that had not met the NAAQS would have to purchase a sufficient amount of emission reduction instruments to offset its contributions of pollution to the region. The *bubble* policy, an early approach in the late 1970s to regulating air emissions, consists of an emission bubble that is placed over several sources of air pollution; the contributions from individual sources can be modulated to meet permitted overall emission levels that can be achieved by accounting for different efficiencies of the individual contributors to that overall bubble. In the EU, the use of economic instruments can complement standard-based command and control methods. A Member State can set targets, but emitters can allocate pollution emissions among themselves and decide on how to meet those targets. In principle, the correct price of noncompliance equates with the government's desired level abatement. The obvious advantage is that sources with lower compliance costs can overcomply and receive economic benefits from those with higher compliance costs; the net result is a

lower net cost to society, compared to command and control measures.

Emission trading and banking is another relatively recent addition to the portfolio of economic instruments used to reduce the emission of pollutants. Emission banking produces pollution credits. These form when there is a gap between the environmental standard and the emissions of pollutants from a firm, if those emissions are below the regulatory standard. Firms can use these credits as if they were currency – they can be banked, transferred, sold, or auctioned under the supervision of the environmental agencies. The environmental standards cannot be exceeded; consequently, the gain, relative to the more uniform command and control system, is that economic efficiency is allowed to work at the level of the firm, stack, or other levels, to minimize pollution and costs and thus generate aggregate societal benefits. The reason for allowing pollution trading through a government-regulated permit system is that those permitted to do so are driven by the market to reduce pollution, increase the efficiency of production, and opt for local or regional flexible control strategies. Specifically, market-based instruments such as pollution permits can accurately account for the different marginal costs of production, technological innovations, and fuel use. The trading system is as follows: a company reduces its emissions below a legal level and thus accrues emission credits that can be used elsewhere or be traded. The economic incentives generated by the trading system contribute to minimizing pollution and increasing the efficiency of production.

Trading is generally based on the sale of pollution permits. This is an activity that, in the United States, is controlled at the state level and can then be left to the market operation, provided that reporting and legally binding standards are met. For example, the CAA, Title I, Section 110(a)(20(A)) allows the states to use such economic instruments as *fees, marketable permits, and the auction of emission rights* to provide incentives, while maintaining competition and economic efficiency. The CAA's Title IV allows electric utilities specifically to trade sulfur dioxide emission allowances, under an emission cap, if emission is below that cap. If the cap is exceeded, the utility doing so loses the allowances and can be fined at levels that are several-fold larger than the

marginal cost of compliance. The statute places monitoring and reporting requirements under the jurisdiction of the US EPA. Under the CAA, economic instruments designed to provide incentives to reduce emissions can be combined. This has been done for acid rain resulting from emission from power generation by burning fossil fuels, principally coal, at the national level. The cap on the total emissions was such that it would result in sulfur dioxide reductions of 10 million tons from the 1980 levels, in 2010. The allowances are based on one ton of sulfur emitted, with the permit system envisioned to operate till the year 2030. The trading of acid rain allowances began in 1993; it included auctions, spot, and advance allowances. The proceeds from auctions are distributed among those from whom allowances were withheld. Trading and caps have also been combined at the state level. In California, the South Coast Air Quality Management District of Los Angeles administers the Regional Clean Air Incentives Market (RECLAIM) under the CAA. It developed a trading system for stationary sources emitting NO_x and SO_x . RECLAIM covers approximately four hundred stationary sources and it is open to sources that generate more than four tons of either of these pollutants per year. This program also uses Best Available Control Technology (BACT) (Rule 2005, Amended May 6, 2005), for new or relocated facilities. In Arizona (Environmental Services Department, 2000), BACT is air pollutant-specific and applies to any new or modified stationary source. For a new source, for instance, BACT is triggered if a new facility can emit more than 150 lbs/day or 25 tons/year of VOCs, NO_x , SO_x or PM; more than 85 lbs day⁻¹ or 15 tons/year or more than 550 lbs/day or 100 tons/year of CO, and so on.

Best Pollution Control Technologies

EU's Council Directive 96/61/EC (1996, integrated pollution prevention and control) gives the following definition for BAT:

'best available techniques' shall mean the most effective and advanced stage in the development of activities and their methods of operation which indicate the practical suitability of particular techniques for providing in principle the basis for emission limit values designed to prevent and, where that is not practicable, generally reduce emissions and the impact on the environment as a whole:

‘techniques’ shall include both the technology used and the way the installation is designed, built, maintained, operated and decommissioned,

– ‘available techniques’ shall mean those developed on a scale which allows implementation in the relevant industrial sector, under economically and technically viable conditions taking into consideration the costs and advantages, ... as long as they are reasonably accessible to the operator,

– ‘best’ shall mean most effective in achieving a high general level of protection of the environment as a whole.

In this context, *emission limit values* are in mass or concentration units. Under the European Parliament Directive 2001/80/EC (limitations of emissions from the air from large combustion plants),

... Member States (of the EU) may require compliance with emission limit values and time limits for implementation which are more stringent than those set out ... They may include other pollutants, and they may impose additional requirements or adaptation of plant to technical progress ... Member States may, without prejudice to this Directive and Directive 96/61/EC, and taking into consideration the costs and benefits as well as their obligations under Directive 2001/81/EC of the European Parliament and of the Council of 23 October 2001 on national emission ceilings for certain atmospheric pollutants (13) and Directive 96/62/EC, define and implement a national emission reduction plan for existing plants, ...

EU Directive 96/61/EC (national emission ceilings for certain atmospheric pollutants), states in its Article 9, as follows:

... the Commission shall report to the European Parliament and the Council ... on the extent to which the interim environmental objectives ... are likely to be met by 2010 and on the extent to which the long-term objectives ... could be met by 2020. The reports shall include an economic assessment, including cost-effectiveness, benefits, an assessment of marginal costs and benefits and the socioeconomic impact of the implementation of the national emission ceilings on particular Member States and sectors. ... They shall take into account the reports made by Member States pursuant to Article 8(1) and (2), as well as, *inter alia*:

- (a) ...
- (b) developments of best available techniques in the framework of the exchange of information under Article 16 of Directive 96/61/EC;
- ...
- (h) any major changes in the energy supply market within a Member State and new forecasts

reflecting the actions taken by Member States to comply with their international obligations in relation to climate change;

...

- (k) new technical and scientific data including an assessment of the uncertainties in:
 - (i) national emission inventories;
 - (ii) input reference data;
 - (iii) knowledge of the transboundary transport and deposition of pollutants;
 - (iv) critical loads and levels;
 - (v) the model used; and an assessment of the resulting uncertainty in the national emission ceilings required to meet the interim environmental objectives mentioned in Article 5.
- ...
- (l) whether there is a need to avoid excessive costs for any individual Member State;
- (m) a comparison of model calculations with observations of acidification, eutrophication and ground-level ozone with a view to improving models;
- (n) the possible use, where appropriate, of relevant economic instruments.”

Article 10 of this Directive also states as under:

All reviews shall include a further investigation of the estimated costs and benefits of national emission ceilings, computed with state-of-the-art models and making use of the best available data to achieve the least possible uncertainty and taking also into account progress in the enlargement of the European Union, and of the merits of alternative methodologies, in the light of the factors listed in Article 9.

According to Pearce [10],

... European studies suggest that benefits exceed costs even for scenarios defined in terms of maximum technologically feasible reduction (MFR) of pollutants, i.e. scenarios in which the most pollutant-reducing technologies are used. Such scenarios should be characterised by very high marginal abatement costs at very high levels of pollution reduction, precisely the context where one would expect incremental benefits to be less than incremental costs. While the benefit cost ratio does appear to fall for such scenarios relative to other more modest abatement targets, the reduction is not dramatic and benefits continue to exceed costs.

In the United States, the Clean Water Act (33 U.S.C. Sections 1251–1387) is intended to assist in the development and implementation of waste treatment management plans and practices to achieve the goals

of the Act. These must provide for waste treatment using the *best practicable technology* before discharging of pollutants to water. To the extent practicable, waste treatment management is area-wide and provides for the control or treatment of all point and nonpoint sources of pollution (Section 1281).

Under the Framework Directive (2000/60/EC), the European Commission develops a list of *priority substances* using the criteria stated in Article 16(2). Specifically, the Commission should prioritize substances:

on the basis of risk to or via the aquatic environment, identified by: (a) risk assessment carried out under Council Regulation n. 793/93, Council Directive 91/414/EEC, and Directive 98/8/EC of the European Parliament and Council, or (b) target risk-based assessment (Council Regulation 793/93), focusing solely on aquatic ecotoxicity and on human toxicity via the aquatic environment.

Moreover, the Commission must take into account the risk assessment performed under other relevant EU legislation. For example, pesticide may be listed as a priority substance under the Framework Directive, but only if the risk assessment found that the pesticide presented a *significant risk to or via the aquatic environment* under the Plant Protection Products Directive [11].

The EU (COM(2006) 70 final 2005 Environment Policy Review (Enhancing New Policy Development)) states as follows in regard to air pollution:

... Thematic Strategy on Air Pollution ... built on an impact assessment by leading experts, 100 stakeholder meetings and a public consultation that drew 11 000 responses. A peer-reviewed, state-of-the-art modelling framework was developed to examine the economic, social and environmental impacts of different potential policies. It examined links between air pollution and other domains: human health, soil acidification, water eutrophication and further action to reduce carbon emissions. Both the thematic strategies and other environmental policies used detailed impact analysis to select the best policy instrument, and included consideration of market-based alternatives to direct regulation. Administrative burden and impacts on competitiveness were analysed, allowing synergies to be identified. For instance, studies for the Waste thematic strategy indicated that best-practice waste minimisation could save manufacturers €2.9-4.2 bn annually. ... Meeting existing objectives at less cost is the rationale behind streamlining (or simplifying) existing legislation.

Conclusions

The alternatives to control exposure to pollution and risks range from command and control measures to economic instruments, and include risk-based strategies. We find that most jurisdictions adopted a risk-cost-benefit rationale to justify how to set standards to eliminate or reduce to an acceptable level, the impact of hazardous conditions. In some cases, the sole expressed legislative concern is with risk elimination or reduction, independent of costs. Yet, even in those situations, the inescapable fact is that it costs time and resources to reduce risks. The statute does not address with respect to costs, that silence is not golden: public money must be spent, others will necessarily be facing less to meet their objectives. We conclude that the preferable way to assess societal choices – for a given objective – is through risk-cost-benefit analysis coupled with the minimization of its expected value. This precept does not exclude alternative ways to rank those choices and adopt other criteria to justify them. The precept provides a common and well-understood method for comparison against other methods and solutions. The ultimate decision is political; the risk-cost-benefit framework is informative and essential, but does not provide the complete answer.

Effect Modification and Interaction

The term *effect modification* has been applied to two distinct phenomena. For the first phenomenon, effect modification simply means that some chosen measure of effect varies across levels of background variables. This phenomenon is thus more precisely termed *effect-measure modification*, and in the statistics literature is more often termed *heterogeneity* or *interaction* [1]. For the second phenomenon, effect modification means that the mechanism of effect differs with background variables, which is known in the biomedical literature as *dependent action* or (again) *interaction*. The two phenomena are often confused, as reflected by the use of the same terms (*effect modification* and *interaction*) for both. In fact they have only limited points of contact.

Effect-Measure Modification (Heterogeneity of Effect)

To make the concepts and distinctions precise, suppose we are studying the effects that change in a variable X will have on a subsequent variable Y , in the presence of a background variable Z that precedes X and Y . For example, X might be treatment level such as dose or treatment arm, Y might be a health outcome variable such as life expectancy following treatment, and Z might be sex (1 = female, 0 = male). To measure effects, write Y_x for the outcome one would have if administered treatment level x of X ; for example, if $X = 1$ for active treatment, $X = 0$ for placebo, then Y_1 is the outcome a subject will have if $X = 1$ is administered, and Y_0 is the outcome a subject will have if $X = 0$ is administered. The Y_x are often called *potential outcomes* (see **Causality/Causation**).

One measure of the effect of changing X from 0 to 1 on the outcome is the difference $Y_1 - Y_0$; for example, if Y were life expectancy, $Y_1 - Y_0$ would be the change in life expectancy. If this difference varied with sex in a systematic fashion, one could say that the difference was modified by sex, or that there was heterogeneity of the difference across sex. Another common measure of effect is the ratio Y_1/Y_0 ;

if this ratio varied with sex in a systematic fashion, one could say that the ratio was modified by sex.

For purely algebraic reasons, two measures may be modified in very different ways by the same variable. Furthermore, if both X and Z affect Y , absence of modification of the difference implies modification of the ratio, and *vice versa*. For example, suppose for the subjects under study $Y_1 = 20$ and $Y_0 = 10$ for all the males, but $Y_1 = 30$ and $Y_0 = 15$ for all the females. Then $Y_1 - Y_0 = 10$ for males but $Y_1 - Y_0 = 15$ for females, so there is a 5-year modification of the difference measure by sex. However, suppose we measured the effects by expectancy ratios Y_1/Y_0 , instead of differences. Then $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/15 = 2$ for females as well, so there is no modification of the ratio measure by sex.

Consider next an example in which $Y_1 = 20$ and $Y_0 = 10$ for males, and $Y_1 = 30$ and $Y_0 = 20$ for females. Then $Y_1 - Y_0 = 10$ for both males and females, so there is no modification of the difference by sex. However, $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/20 = 1.5$ for females, so there is modification of the ratio by sex.

Finally, suppose $Y_1 = 20$ and $Y_0 = 10$ for males, and $Y_1 = 60$ and $Y_0 = 40$ for females. Then $Y_1 - Y_0 = 10$ for males and $Y_1 - Y_0 = 20$ for females, so the Y difference is smaller among males than among females. However, $Y_1/Y_0 = 20/10 = 2$ for males and $Y_1/Y_0 = 30/20 = 1.5$ for females, so the Y ratio is larger among males than among females. Thus, modification can be in the opposite direction for different measures of effect.

Biologic Interaction

The preceding examples show that one should not, in general, equate the presence or absence of effect-measure modification to the presence or absence of interactions in the biologic (mechanistic) sense, because effect-measure modification depends entirely on what measure one chooses to examine, whereas the mechanism is the same regardless of that choice. Nonetheless, it is possible to formulate mechanisms of action that imply homogeneity (no modification) of a particular measure. For such a mechanism, the observation of heterogeneity in that measure can be taken as evidence against the mechanism (assuming of course that the observations are valid). It would be fallacious, however, to infer the mechanism is correct

if homogeneity was observed, for the usual reason that many other mechanisms (some unimagined) would imply the observation.

A classic example is the simple “independent-action” model for the effect of X and Z on Y , in which subjects affected by changes in X are disjoint from subjects affected by changes in Z [2, 3]. This model implies homogeneity (*absence* of modification by Z) of the average X effect on Y when that effect is measured by the difference in the average Y . In particular, suppose Y is a disease indicator (1 if disease occurs, 0 if not). Then the average of Y is the proportion getting disease (the incidence proportion, often called the *risk*) and the average Y difference is the risk difference. Thus, in this context, the independent-action model implies that the risk difference for the effect of X on Y will be constant across levels of Z ; in other words, the risk difference will be homogeneous across Z , or unmodified by Z .

If X and Z both have effects, this homogeneity of the difference forces ratio measures of the effect of X on Y to be heterogeneous across Z . When additional factors are present in the model (such as confounders) homogeneity of the risk differences can also lead to heterogeneity of the excess risk ratios [4]. Thus, under the simple independent-action model, the independence of the X and Z effects will cause the measures other than the risk difference to be heterogeneous, or modified, across Z .

Biologic models for the mechanism of X and Z interactions can lead to other patterns. For example, certain multistage models in which X and Z act at completely separate stages of a multistage mechanism can lead to homogeneity of ratios rather than differences, as well as particular dose–response patterns. Special caution is needed in interpreting observed patterns, however, because converse relations do not hold. Many different plausible biologic models will imply identical patterns in the effect measures [5].

Synergism and Antagonism

Taking the simple independent-action model as a baseline, one may offer the following *dependent-action* definitions for an outcome indicator Y as a function of the causal antecedents X and Z . *Synergism* of $X = 1$ and $Z = 1$ in causing $Y = 1$ is defined as necessity and sufficiency of $X = 1$ and $Z = 1$ for causing $Y = 1$, i.e., $Y = 1$ if and only if $X = 1$ and $Z = 1$. We may also say that $Y = 1$ in

a given individual would be a synergistic response to $X = 1$ and $Z = 1$ if $Y = 0$ would have occurred instead if either $X = 0$ or $Z = 0$ or both. In potential-outcome notation where Y_{xz} is the outcome when $X = x$ and $Z = z$, this definition says synergistic responders have $Y_{11} = 1$ and $Y_{10} = Y_{01} = Y_{00} = 0$. *Antagonism* of $X = 1$ by $Z = 1$ in causing $Y = 1$ is defined as necessity and sufficiency of $Z = 0$ in order for $X = 1$ to cause $Y = 1$. This definition says antagonistic responders to X or Z have $Y_{10} = 1$ or $Y_{01} = 1$ or both, and $Y_{11} = Y_{00} = 0$.

With these definitions, synergism and antagonism are not logically distinct concepts, but depend on the coding of X and Z . For example, switching the labels of “exposed” and “unexposed” for one factor can change apparent synergy to apparent antagonism, and *vice versa* [1, 2]. The only label-invariant property is whether the effect of X on a given person is altered by the level of Z , i.e., the action of X is dependent on Z . If so, by definition we have biologic interaction.

Absence of any synergistic or antagonistic interaction among levels of X and Z implies homogeneity (*absence* of modification by Z) of the average X effect across levels of Z when the X effect is measured by the differences in Y across levels of X [2, 6]. The converse is false, however. Homogeneity of the difference measures (e.g., lack of modification of the risk difference) does not imply absence of synergy or antagonism, because such homogeneity can arise through other means (e.g., averaging out of the synergistic and antagonistic effects across the population being examined).

A more restrictive set of definitions is based on the sufficient-component cause model of causation [1, 7]. Here, *synergism* of the indicators X and Z is defined as the presence of $X = 1$ and $Z = 1$ in the same sufficient cause of $Y = 1$, i.e., the sufficient cause cannot act without both $X = 1$ and $Z = 1$. Similarly, *antagonism* of $X = 1$ by $Z = 1$ is defined as the presence of $X = 1$ and $Z = 0$ in the same sufficient cause of $Y = 1$. These definitions are also coding dependent.

Extensions to Continuous Outcomes

The use of indicators in the above definitions may appear restrictive but is not. For example, to subsume a continuous outcome T such as death time, we may define Y_t as the indicator for $T \leq t$ and apply the above definitions to each Y_t . Similar devices can be

applied to incorporate continuous exposure variables [6]. The resulting set of indicators is of course unwieldy, and in application has to be simplified by modeling constraints (e.g., proportional hazards for T).

Noncausal (Statistical) “Interaction”

Both the preceding usages of “effect modification” and “interaction” refer to causal phenomena (see **Causality/Causation**). In the statistics literature, “interaction” is often used without explicit reference to causality. For example, in the context of regression modeling, an “interaction term” is usually nothing more than a term involving the product of two or more variables. Consider a *logistic regression* (see **Logistic Regression**) to predict a man’s actual sexual preference A ($A = 1$ for men, 0 for women) from his self-reported preference R and the interviewer’s gender G ($G = 1$ for male, 0 for female),

$$P(A = 1|R, G) = \text{expit}(\alpha + \beta R + \gamma G + \delta \cdot R \cdot G) \quad (1)$$

where $\text{expit}(x) = e^x/(1 + e^x)$ is the logistic function. Such a model can be useful in correcting for misreporting. The term $\delta \cdot R \cdot G$ (or sometimes just $R \cdot G$ or just δ) is often called an *interaction term*. It is, however, more accurately called a *product term*, for presumably, neither self-report nor interviewer status has any causal effect on actual preference, and thus cannot interact causally or modify each other’s effect (since there is no effect to modify).

If $\delta \neq 0$, the product term implies that the regression of A on R depends on G : for male interviewers the regression of A on R is

$$P(A = 1|R, G = 1) = \text{expit}(\alpha + \beta R + \gamma \cdot 1 + \delta \cdot R \cdot 1) = \text{expit}(\alpha + \gamma + (\beta + \delta)R) \quad (2)$$

whereas for female interviewers the regression of A on R is

$$P(A = 1|R, G = 0) = \text{expit}(\alpha + \beta R + \gamma \cdot 0 + \delta \cdot R \cdot 0) = \text{expit}(\alpha + \beta R) \quad (3)$$

Thus we can say that the gender of the interviewer affects or modifies the logistic regression of actual preference on self-report. Nonetheless, since

neither interviewer gender nor self-report affect actual preference (biologically or otherwise), they have no biologic interaction.

When both the factors in the regression do causally affect the outcome, it is common to take the presence of a product term in a model as implying biologic interaction, and conversely to take absence of a product term as implying no biologic interaction. Neither inference is correct. The size and even direction of the product term can change with choice regression model (e.g., linear *versus* logistic), whereas biologic interaction is a natural phenomenon oblivious to our choice of model for analysis [1, 8]. Assuming no bias is present, however, a product term in a linear statistical model for a causal dependency can only arise from the presence of biologic interaction in the dependent-action sense [1, 2].

Efficacy

The primary objective of a clinical trial (*see* **Randomized Controlled Trials**) is generally to establish the efficacy, or true biologic effect, of a new treatment or intervention [1]. The randomized controlled trial in which the new treatment or intervention is compared with a standard treatment or placebo is the gold standard to accomplish this objective. Efficacy is distinct from effectiveness (i.e., the effect of a treatment or intervention when widely used in practice) [1].

A key consideration in the design of comparative efficacy or phase III trials is the selection of the primary efficacy endpoint or outcome for evaluation [2]. This choice depends on the nature of the disease, the nature of the treatment, the duration of the treatment, the expected effects of the treatment, and the time frame for the expected effect. The hypothesis to be tested, the study design, and the sample size are all based on the measurement of the specified endpoint and on the difference between the new treatment group and the standard or placebo group that is considered meaningful.

These endpoints can include response rates to treatments such as cure rates, mortality or survival rates, and continuous variables such as changes from baseline in blood pressure or cholesterol levels. The efficacy evaluation is based on the comparison of these outcomes in the treatment and control groups. For example, the difference in the complete response rates after 4 months of chemotherapy on a new treatment and the standard treatment provides an estimate of the efficacy of the new treatment; the difference between the new and standard treatments in change in diastolic blood pressure from baseline levels after 8 weeks of therapy provides an estimate of the efficacy of the new agent. The difference in mortality or survival rates between the two groups can be used to estimate efficacy. In the presence of censored data, median survival times or the relative risk of death in the two groups can be used to estimate the efficacy of the new treatment compared to the standard one.

Composite or combined endpoints are also often used to evaluate efficacy. For example, we might consider the outcome of a long-term trial to be time to the first occurrence of a nonfatal myocardial infarction, coronary bypass surgery or stent placement for

unstable angina, or mortality from cardiovascular disease.

Ideally, the endpoints to assess efficacy should be obtained for all randomized patients or subjects, and should be unambiguous and verifiable. These measures should be validated and meet expected criteria for accuracy, reproducibility, reliability, and consistency over time [3]. In some circumstances, the assessment of efficacy requires long-term follow-up, and surrogate endpoints are considered for the efficacy evaluation. The criteria for the use of a surrogate endpoint require that it be correlated with the clinical endpoint of interest (e.g., mortality) and capture the effect of the treatment or intervention on the clinical endpoint so that it can be reliably used as a replacement [4]. In early clinical trials to evaluate HIV therapies, CD4+ counts were used as surrogate markers for mortality; subsequently, these counts were found not to be associated with mortality [5].

The evaluation of the efficacy of a new vaccine that is administered to healthy individuals is associated with additional complexities. Preventive vaccine trials are large and the event rates are generally relatively low even in a placebo group. The usual measure of vaccine efficacy (or effectiveness) is estimated as the percentage reduction in disease incidence attributable to the new vaccine, i.e.,

$$\left[1 - RR \left(\frac{\text{vaccinated individuals}}{\text{placebo controls}} \right) \right] \times 100\%$$

where RR is the relative risk. For a discussion of the complexities of intent-to-treat effectiveness studies and per-protocol efficacy studies, see Horne *et al.* [6].

The interpretation of the efficacy results from any trial depends on the conduct of the trial as well as the analysis. The risks of reaching incorrect conclusions regarding the efficacy of a new treatment are increased as the deviations from the planned design and randomization increase. When the intent to treat and the per-protocol or as-treated populations do not differ in any major ways, then the risks of incorrectly attributing efficacy (or lack of efficacy) to a new treatment are reduced.

Summary

We have reviewed the general concepts involved in the evaluation of efficacy from randomized controlled clinical trials. The criteria for the use of surrogate

endpoints and the special issues in vaccine efficacy are noted.

Engineered Nanomaterials

Nanotechnology is a generic term encompassing technologies that depend on manipulating matter at the nanoscale, to produce new materials, devices, and products. It bridges many scientific disciplines, often leading to new and innovative applications. Engineered nanomaterials are a product of nanotechnology, and have an intentionally produced structure at the scale of approximately 1–100 nm. The simplest engineered nanomaterials include compact particles within this size range, formed from single elements or compounds. More complex nanomaterials include nonspherical particles such as carbon nanotubes, and heterogeneous particles such as silver-coated titanium dioxide. Engineered nanomaterials also include aggregated forms of these particles, composites incorporating nanoscale materials, and materials with engineered nanoscale voids. These materials are designed to demonstrate properties that depend on a carefully controlled and implemented nanostructure.

Risk Assessment Challenges

The close dependency between structure and functionality challenges how quantitative risk assessment is applied to these new materials. Nanostructure-dependent properties may lead to health risks that not only depend on chemistry- and mass-based dose, but also on structure-related properties that include particle size, surface area, and shape. Studies have shown that poorly soluble nanostructured materials in rodent lungs can elicit a response that is associated with surface area and surface chemistry, and there is evidence that the size, surface chemistry, and possibly shape of nanomaterials may determine transport through the body and even into cells [1]. Quantitative risk assessment of engineered nanomaterials will depend on determining when they behave differently from conventional materials, what properties are associated with their potential impact, and how exposure, dose and response can be most appropriately evaluated.

Not every engineered nanomaterial will present new challenges. Maynard and Kuempel [2] have proposed that an emphasis should be placed on nanomaterials that can enter the body in some form and

have the potential to exhibit nanostructure-dependent biological behavior. These include powders, suspensions, and slurries of nanometer-scale particles, as well as nanostructured aggregates of these particles if they are sufficiently small to be inhaled or ingested. Other engineered nanomaterials, such as those where nanostructured particles that could potentially enter the body might be released, may require special attention. For instance, machining engineered nanomaterial composites may release airborne nanostructured particles that can be inhaled; and abrasion of engineered nanomaterial surface coatings may release nanostructured materials that are biologically available.

Research is ongoing to support the quantitative risk assessments of engineered nanomaterials. Where these new materials behave in unexpected ways, new information is needed on hazard assessment, dose evaluation, and exposure characterization [3]. In many cases, it is likely that structure-related attributes such as particle size, shape, surface area, and surface chemistry will be more important than mass and chemical composition in determining potential risk [4].

Summary

The challenges of quantifying risks presented by some engineered nanomaterials will most likely continue for many years, particularly as these materials become increasingly sophisticated. Simple solutions are unlikely, given the number of interrelated parameters that may influence potential health impact. Until more comprehensive information is available, it will be necessary to identify those engineered nanomaterials that present unique challenges, and to use existing information together with expert extrapolation as a basis for qualitative and semi-quantitative risk assessment [5, 6].

Enterprise Risk Management (ERM)

Definition

Enterprise risk management (ERM) is a recent risk-management technique, practiced increasingly by large corporations in industries throughout the world. It was listed as one of the 20 breakthrough ideas for 2004 in Harvard Business Review [1]. ERM reflects the change of mind-set in risk management over the past decades. Business leaders realize that certain risks are inevitable in order to create value through operations, and some risks are indeed valuable opportunities if exploited and managed effectively. Sensible risk management flows from the recognition that a dollar spent on managing risk is a dollar cost to the firm, regardless of whether this risk arises in the finance arena or in the context of a physical calamity such as fire. ERM thus proposes that the firm addresses these risks in a unified manner, consistent with its strategic objectives and risk appetite.

Most corporations adopt the definition of ERM proposed by the Committee of Sponsoring Organizations of the Treadway Commission (COSO) in their 2004 ERM framework [2]. It intended to establish key concepts, principles, and techniques for ERM. In this framework, ERM is defined as “a process, affected by an entity’s board of directors, management and other personnel, applied in strategy setting and across the enterprise, designed to identify potential events that may affect the entity, and manage risk to be within its risk appetite, to provide reasonable assurance regarding the achievement of entity objectives”. This definition highlights that ERM reaches the highest level of the organizational structure and is directed by corporations’ business strategies. The concept of risk appetite is a crucial component of the definition. Risk appetite reflects a firm’s willingness and ability to take on risks in order to achieve its objectives. Once it is established, all subsequent risk-management decisions will be made within the firm’s risk appetite. Thus, the articulation of risk appetite greatly affects the robustness and success of an ERM process. Different themes of business objectives are applied to determine risk appetite. Among the most common ones are solvency concerns, ratings concerns, and earnings volatility concerns [3]. The

themes directing the risk appetite process should be consistent with the corporation’s risk culture and overall strategies.

Despite its wide acceptance, the COSO definition is not the only available definition. For example, the casualty actuarial society (CAS) offered an alternative definition in its 2003 overview of ERM [4]. In CAS’s definition, “ERM is the discipline by which an organization in any industry assesses, controls, exploits, finances, and monitors risks from all sources for the purpose of increasing the organization’s short- and long-term value to its stakeholders”. Individual corporations may also define ERM uniquely according to their own understanding and objectives. Creating a clear, firm-tailored definition is an important precursor to the firm implementing a successful ERM framework. In fact, a 2006 survey of US corporations identified that lack of an unambiguous understanding of ERM is the one obstacle preventing companies from putting ERM in place [5].

Current Development of ERM

As a rising management discipline, ERM varies across industries and corporations. The insurance industry, financial institutions, and the energy industry are among the industry sectors where ERM has seen relatively advanced development in a broad range of corporations [6]. The enforcement of ERM in these industries was originally stimulated by regulatory requirements. Recently, more corporations in other industries, and even the public sector, are becoming aware of the potential value of ERM and risk managers are increasingly bringing it to top executives’ agendas. According to a 2006 survey of US corporations, over two-thirds of the surveyed companies either have an ERM program in place or are seriously considering adopting one [5]. An earlier survey of Canadian companies obtained similar results. It found that over a third of the sample companies were practicing ERM in 2003 and an even larger portion of the sample companies were moving in that direction [7]. For a detailed case study in the corporate use of ERM, see Harrington and Niehaus [8] on United Grain Growers.

ERM Implementation

Notwithstanding the attractiveness of ERM conceptually, corporations are often challenged to put it

into effect. One of the main challenges is to manage the totality of corporation risks as a portfolio in the operational decision process, rather than as individual silos, as is traditionally done. Several specific aspects of ERM implementation together with present challenges are considered below.

Determinants of ERM

Although ERM is largely considered as an advanced risk-management concept and toolkit, it is carried out at different paces by corporations. Studies have examined corporate characteristics that appear to be determinants of ERM adoption. For example, Liebenberg and Hoyt [9] found that firms with greater financial leverage are more likely to appoint a chief risk officer (CRO), a signal for their adoption of ERM. In another study, factors including presence of CRO, board independence, chief executive officer (CEO) and chief financial officer (CFO) support for ERM, use of Big Four auditors, and entity size were found to be positively related to the stage of ERM adoption [6]. These factors reflect ERM's role in corporate governance: launch and pursuit of the ERM process lead to better corporate governance, which is desired by both external and internal constituencies.

Operationalization of ERM

The core of the challenge lies in operationalizing ERM in practice. Integration of risks is not merely a procedure of stacking all risks together, but rather a procedure of fully recognizing the interrelations among risks and prioritizing risks to create true economic value. Important components of this procedure include risk identification, risk measurement, risk aggregation/other modeling approaches, risk prioritization, and risk communication.

Risk Identification. The four major categories of risks considered under an ERM framework are hazard risk, financial risk, operational risk (*see Operational Risk Modeling*), and strategic risk [4]. Hazard risk refers to physical risks whose financial consequences are traditionally mitigated by purchasing insurance policies. Examples of hazard risk include fire, theft, business interruption, liability claims, etc. Financial risk refers to those risks involving capital and financial market. Market risk (interest rate risk, commodity risk, and foreign exchange risk) and

credit risk (default risk) are among the most important financial risks. This type of risk is usually hedged by financial instruments, such as derivatives. Operational risk (in Basel II, operational risk is defined as “the risk of loss resulting from inadequate or failed internal processes, people and systems or from external events”) is a nascent risk category and has inspired increasing interest. Operational risk includes internal fraud, external fraud, employment practices and workplace safety, clients, products and business practices, damage to physical assets, business disruption and system failures, execution, delivery, and process management [10]. The newly released Basel Capital Accord II [10] first drew attention to operational risk in the banking industry. The impact soon spread to other industries and now operational risk is ranked as the most important risk domain by US corporate executives [5]. However, given the complex and dynamic nature of operational risk, there is no easy solution: effective risk management of operational risks requires sophisticated and innovative risk-management techniques. Finally, strategic risk is more directly related to the overall strategies of corporations. It includes reputation risk, competition risk, regulatory risk, etc. The management of strategic risk does not automatically fall into standard categories of risk-management techniques. Specific risks perceived by each corporation need to be identified and managed customarily.

Under ERM, the identification of individual risks in different categories should facilitate successive prioritization and integration of risks to best achieve business objectives within the corporation's risk appetite. Moreover, not all risks that are likely to face the corporation fall into one of the above major categories. Any event that may adversely affect the corporation's achievement of its objectives is considered a risk under ERM. Therefore, proper objective identification is a prerequisite for risk identification. For example, business objectives can be described by certain key performance indicators (KPIs), which are usually financial measures such as return on equity (ROE), operating income, earnings per share (EPS), and other metrics for specific industries, e.g., risk adjusted return on capital (RAROC) and risk-based capital (RBC) for financial and insurance industries [4]. Risks are then recognized by means of these company performance metrics. This is the first step to implement a sound ERM process.

Risk Aggregation and Risk Measures. A central step toward operationalizing ERM is to establish a modeling approach for risk integration. The study by Holmer and Zenios [11] is among the earliest studies that shed light on value creation by process integration/holistic management. They proposed an approach that integrates different parts of the production process (designing, pricing, and manufacturing) to improve productivity of financial intermediaries. Although risk management was rarely involved in that work, the underlying rationale is essentially the same.

A sensible way to unify and integrate different types of risks is to derive the total risk (loss) distribution. The process starts with individual risks, which, as random variables, are usually represented by certain probability distribution functions. An aggregated risk distribution for the entire corporation can be derived from these individual risk distributions. A risk measure is then developed to reflect the risk level, e.g., the risk measure can be denoted in dollar terms, in the form of capital requirements. This risk aggregation approach is especially useful for financial firms and insurers, where the goal is to calculate regulatory or economic capital based on the aggregated risk distribution.

Aggregated risk distribution functions are essentially described by the marginal distributions of individual risks and the interrelations (or dependence structure) among the risks. Marginal distributions are found for each identified individual risk through parametric models, nonparametric models, or stochastic simulations [12]. Parametric models fit certain predetermined distribution functions to data using techniques such as maximum-likelihood estimation (MLE) or minimum mean squared error (MSE) estimation. Nonparametric models rely on histogram or smoother-based (e.g., kernel density) estimation from historical data. Stochastic simulation methods repeatedly sample from the distributions of random input variables to build up joint distributions of output quantities. Among these methods, stochastic simulation methods have become increasingly popular in both academia and practice.

There are also multiple ways to capture the interrelations among risks. A simple approach is through variance–covariance matrices. Correlations among different risks are either calculated on the basis of historical data or conjectured by domain experts. Alternatively, structure simulation models

can be employed to link possibly correlated risks to common factors [4]. For example, certain macroeconomic conditions may drive multiple market risks and thus result in interactions among them. Interrelations among risks can be exploited to take advantage of natural hedges and to place early warnings on catastrophic events where different types of risks strike together, which may lead to real economic benefits created by ERM.

At a slightly more sophisticated level, dependence structures among risks can be modeled using *copulas* (see **Copulas and Other Measures of Dependency**). Suppose we have two risks X and Y with marginal distribution functions $F_X(x)$ and $F_Y(y)$. Denote their joint distribution function by $F_{X,Y}(x, y)$. Then a copula [13] is obtained as

$$C(u, v) = F_{X,Y}(F_X^{-1}(u), F_Y^{-1}(v)) \quad (1)$$

Various types of copulas (for example, normal copula or student- t copula) can be employed together with different choices of marginal distributions to derive joint distribution functions.

Among the available risk measures, quantile-based measures are perhaps the most prevalent currently. This class of risk measures focus on the tail area of the distribution functions, i.e., those events occurring with low probabilities but are associated with large losses should they occur, which reflect an intention to protect shareholders' value in the event of default or insolvency. The well-known *value-at-risk* (VaR) (see **Value at Risk (VaR) and Risk Measures**) measure is of this type. VaR is the maximum loss that might be suffered at a given confidence level (e.g., 95%) over a certain period of time (e.g., one trading day). Mathematically, VaR at the α confidence level is the α quantile of the loss distribution function $F_X(x)$, or

$$\text{VaR}_\alpha = F_X^{-1}(\alpha) \quad (2)$$

Although VaR measures are extensively employed, especially in financial risk management, doubts have been raised on its ability to depict a complete risk picture as a “coherent” risk measure,^a meaning a risk measure satisfying several normative axioms [12]. One of the most important concerns is that VaR, in general, fails to satisfy the subadditivity property^b for coherent risk measures, except under special distributional assumptions such as the multivariate normal distribution [14].

A closely related alternative measure, expected shortfall (or loosely, tail-VaR), is proposed to make up for the possible shortcomings of VaR. Expected shortfall takes into account not only the probability of adverse events, as VaR does, but also the average magnitude of these events. Mathematically,

$$ES_\alpha = \frac{1}{1-\alpha} \int_\alpha^1 F_x^{-1}(p) dp \quad (3)$$

where α is the confidence level.

Further considerations lead to other classes of risk measures. For example, the so-called spectral risk measures [15] incorporate a weighting function to describe different degrees of risk aversions on quantiles. In this sense, expected shortfall is imperfect since it assigns equal weight ($\frac{1}{1-\alpha}$) to the entire $(1-\alpha)$ region (and a weight of zero outside the region), implying risk neutrality rather than risk aversion in the region. Moreover, an important risk measure based on the distorted distribution functions was developed by Wang [16, 17]. The distorted survival function of the loss $S^*(x)$ is produced by applying a distortion function $g(\cdot)$ to the original survival function $S(x)$:

$$S(x) = 1 - F(x) \quad (4)$$

$$S^*(x) = g[S(x)] \quad (5)$$

where $F(x)$ is the distribution function and g is an increasing function with $g(0) = 0$ and $g(1) = 1$.

Wang [16, 17] suggests specific choices of the distortion function $g(\cdot)$:

$$g(u) = \Phi[\Phi^{-1}(u) + \lambda] \quad (6)$$

and

$$g(u) = Q[\Phi^{-1}(u) + \lambda] \quad (7)$$

where Φ is the standard normal distribution function, Q is the student- t distribution function, and λ is the market price of risk parameter. Formula (6) is also known as the *Wang transform*. A coherent risk measure can be then developed by taking expectation with respect to the distorted distribution function.^c Risk measures can also be formed to account for other parts of the distribution functions rather than the tail, e.g., they can be formed on the basis of expected utilities (see **Axiomatic Measures of Risk and Risk-Value Models**).

In practice, simplified approaches are sometimes adopted to obtain the aggregated risk measure. For example, one can derive the portfolio VaR as a weighted sum of VaR for each component risk, which implies perfect correlation between risks, or sometimes, multivariate normality is assumed for the individual risk components and a VaR measure is obtained accordingly. However, these simplified measures should be used with caution since they may lead to biased total risk estimation in some situations [13].

Risk Prioritization. To realize effective risk integration, ERM also promotes risk prioritization. Risk prioritization stems from the fact that risks are not equally important to corporations. Prioritization should reflect different aspects of the company's strategies and risk-management philosophy, e.g., cost to tolerate that risk, reduce it, elicit and apply management's risk preferences, etc.

A two-dimensional risk map (see Figure 1) can be used to rank risks. The vertical axis represents impact of the underlying risks (the severity of losses) and the horizontal axis represents likelihood of the underlying risks (the frequency of losses). Different alert levels and risk-management strategies are placed on each quarter panel. The low-likelihood, low-impact area usually needs minimum alarm; the high-likelihood, low-impact area should be dealt with accordingly

Figure 1 A two-dimensional risk map. The horizontal axis represents loss likelihood and the vertical axis represents loss impact. The four quarter panels stand for different combinations of likelihood and impact. Different colors are used to illustrate the overall impact of risks in each quarter panel to the corporation. Dark gray and black zones usually raise much higher concerns than the light gray and white zones. This map is used in prioritizing risks and designing risk-management techniques accordingly

by the risk-management routine (e.g., risk retention); the low-likelihood, high-impact area requires appropriate monitoring and special risk-management techniques (e.g., insurance); the high-likelihood, high-impact area can be disastrous to the corporation and thus demands full alert and tight control (e.g., risk avoidance) [18]. According to the ranking suggested by the risk map, corporations may want to prioritize those risks with high impact, as they may bring down the entire corporation if incurred. Risk-management activities should then be executed on the basis of assigned priority and characteristics of risks.

Alternatively, risks can also be ranked and prioritized on the basis of their respective impact on KPIs [4]. As explained above, KPIs describe corporations' strategic targets. The ultimate aim of ERM is to assist corporations in achieving these strategic targets by managing risks in the most effective way. Thus, risks that have higher potential influence on KPIs (or other chosen measures of objectives) should be prioritized and treated with special focus.

Risk Reporting and Risk Communications. Despite the extensive attention given to its technical aspects, ERM is not just about numbers. A key factor for success is effective risk communication (*see Role of Risk Communication in a Comprehensive Risk Management Approach*) from the board and executive management to operational units, and across different business departments of corporations. One way to implement and improve risk communication is through a well-designed risk reporting system [19]. The risk reporting system should both provide succinct summaries of critical risk information covering the broad range of corporate risks for board members and executives and allow access to more detailed information for those responsible for specific risks at the operational level. Moreover, both qualitative and quantitative analysis should be incorporated into a single system.

ERM software has been developed for this purpose. For example, an ERM dashboard, an interface providing "role-based information to key decision makers" is recommended for risk reporting [19]. Risk registers are also widely used for risk reporting and management. Risk registers record relevant information including risks, risk assessments, impact on KPIs, risk-management tools, and responsible personnel, to keep track of the risk-management activities and allow interactions among different parties

[18]. There are also other commercial ERM software products that are under development for general use or for use by particular corporations.

ERM and Compliance

ERM at first arises from corporations' efforts to comply with laws and regulations. To this end, ERM is seen more as an efficient internal control process. Within a corporation, it is often conducted with internal control functions and supervised by internal auditors. The most significant regulatory forces responsible for the rise of ERM are the Sarbanes Oxley Act of 2002, the Basel Capital Accord II, and rating criteria set forth by rating agencies such as Standard & Poor's (S&P).

Sarbanes Oxley Act of 2002

In the United States, the Sarbanes Oxley Act of 2002 [20] greatly raised compliance difficulty for corporations. Section 404 of the act governs the corporations' internal control activities over financial reporting and disclosure to the public. External auditors are also involved in assessing and certifying the adequacy of corporations' internal controls. Corporations have invested great amounts of time and money to comply with the act. In this process, they turn to ERM as a solution to the need for adequate, well reasoned and documented, and efficient internal controls, rather than for general risk-management purposes. Meanwhile, Sarbanes Oxley Act itself poses compliance risks for many corporations. ERM can potentially provide an effective toolkit for managing this type of risk.

Basel Capital Accord II

The Basel Capital Accord II [10] has also probably contributed to the development of ERM. This new Basel Capital Accord clearly describes the determination of capital requirements for the banking industry from a regulatory point of view. Besides minimum capital requirements, it also highlights the importance of supervisory review processes for managing major risks. Also for the first time, Basel II explicitly reflects regulatory interest in operational risk. Regulatory capital requirements and review process should stipulate ERM adoption by corporations,

to attain unification of risk and capital management, and to fulfill compliance needs.

Rating Agency

As a major constituency for corporations, rating agencies may have a more direct influence on promoting ERM practice as compared to the previous two forces. S&P started to evaluate ERM practice and incorporate it in the rating process for insurers in 2005 [21] and refined the criteria in 2006 [22]. The rating criteria span important components of the ERM process. Risk-management culture, risk control techniques, methodologies and principles employed by risk models, and the ability to deal with emerging risks all contribute to insurers' overall ERM assessment. S&P also gives positive weight to the articulation of risk appetite (and resulting risk tolerance, risk limits, etc.) because of its fundamental role in the ERM process.

In 2006, S&P extended its ERM evaluation to the financial industry by developing rating criteria specifically for financial institutions [23]. The ERM assessment framework is built up in three dimensions: infrastructure, policies, and methodology. The evaluation process focuses on five aspects: risk governance, operational risk, market risk, credit risk, and funding and liquidity. Among these, risk governance includes risk culture, risk appetite, risk aggregation/quantification, and risk disclosure. Highly rated financial institutions are those that use effective methodologies and procedures to control each important category of risks and that have a holistic view of the overall risk profile. S&P's rating criteria will undoubtedly encourage continuous adoption and elaboration of ERM in these industries. Moreover, it is likely that rating agencies will start to establish rating criteria for general industries in the foreseeable future, which will provide an even stronger incentive for corporations to aggressively advance in the ERM process.

Conclusion: ERM Future – Value Creation

ERM practices may have been initially driven by compliance needs, but ERM development should continue to serve as an internal control function for better corporate governance. Furthermore, the forces upon which ERM thrives are related to the potential economic value generated by better managing risks under identified objectives. One

common objective for corporations is to maximize firm value. ERM provides a framework for corporations to consciously optimize the risk/return relationships for their businesses. This optimization is achieved through the alignment of corporate strategic goals and risk appetite. At the operational level, the alignment guides virtually all activities conducted by the corporation. Specific risks are identified and measured. They are prioritized and integrated by recognizing the interrelations and relative influences affecting different risky outcomes. Risk-management strategies are developed for the entire portfolio of risks and their effects are assessed and communicated. In this way, ERM can reduce waste of resources caused by inadequate communication and cooperation under silo-based risk-management frameworks. ERM can also increase the capacity and free up space for new opportunities to be explored. In addition to these two primary sources of value, more effective risk management also creates benefits from higher credit ratings, lower distress costs, more favorable contract provisions, etc.

Testing the added value of ERM itself is another present challenge. Wang [17] proposes that value creation can be calculated as the increase in economic value of the portfolio after implementing ERM, where the economic value is obtained by discounting the expected net revenue using the distorted distribution function. Zenios [24] demonstrates using operations research methods that effective integration of risks under ERM can create value by pushing out the risk/reward frontier of the entire portfolio. More theoretical and empirical analyses are needed to demonstrate/test the added value from ERM.

ERM is still at an early stage of development. Conceptual and practical frameworks are still being constructed through the combined efforts of regulators, industries, and academia. More advanced methodologies, techniques, and tools are rapidly emerging. Therefore, some of the aspects (e.g., what ERM is, its real effects, in what way it can be best implemented, etc.) described will become refined and clarified as advances accumulate, allowing more concrete and analytical discussions.

End Notes

^a. A coherent risk measure should satisfy a set of properties: monotonicity, subadditivity, positive

homogeneity, and translation invariance. For details, see Artzner *et al.* [25].

^b. For any risks X and Y , a risk measure ρ is said to be subadditive if $\rho(X + Y) \leq \rho(X) + \rho(Y)$, which implies that portfolio risk should be no greater than the sum of individual component risks.

^c. Readers interested in quantile-based measures are directed to Dowd and Blake [12].

Considerations in Planning for Successful Risk Communication Early Warning Systems (EWSs) for Predicting Financial Crisis

JING AI AND PATRICK L. BROCKETT

Environmental Carcinogenesis Risk

Cancer is a major public health concern, with approximately one-half of all men and one-third of all women likely to develop the disease during their lifetime [1]. Cancer is the second leading cause of death in the United States [2], with approximately 200 deaths per year per 100 000 population (all ages, genders, and races combined). The causes of cancer are complex and multifactorial, involving genetic factors and natural aging. However, scientists agree that a significant proportion of cases are likely attributable to the environment, especially when broadly interpreted to include lifestyle choices such as smoking and diet, as well as chemical exposures encountered in the workplace, air, water, or in our food (see **Air Pollution Risk**; **Water Pollution Risk**).

There are several excellent sources of information about known cancer causing agents, or carcinogens. For example, in response to a U.S. Congressional mandate, the National Toxicology Program (NTP; see <http://ntp-server.niehs.nih.gov/>) reports biennially on all substances that are known or suspected to be human carcinogens, and also issues a periodic *Report on Carcinogens* [2]. The International Agency for Research on Cancer (IARC; see <http://www.iarc.fr/>) is another excellent source.

Both the NTP and IARC distinguish substances for which there is clear evidence of carcinogenicity in humans from those where carcinogenicity is suspected, but not confirmed. Suspicion of carcinogenicity in humans may be based on experimental data in animals (see **Cancer Risk Evaluation from Animal Studies**) or knowledge of the chemical structure and function of the compound itself. Classification as a known carcinogen usually requires the existence of reliable epidemiological data. Not surprisingly, the list of known and suspected carcinogens is relatively small. Classifications can also change over time in response to evolving science. For example, while the 2000 report listed 65 known carcinogens, this number was reduced to 58 for the 2005 report [3]. Saccharin is a high profile substance that was listed as a suspected carcinogen in the eighth report [4], but subsequently delisted. Among some of the more familiar known carcinogens

are cigarette smoke (see **Environmental Tobacco Smoke**), radon (see **Radon Risk**), solar radiation, aflatoxins, several metals (see **Arsenic**, cadmium), a variety of air pollutants products (1,3-butadiene, soot, coke oven emissions), several chemotherapeutic agents (e.g. tamoxifen, thiotepa) and some dyes. The list of suspected carcinogens is much longer. Almost always, the basis of the latter listing are positive findings in controlled animals experiments, although data from studies of human populations is also important in this regard. Statistical methodology to support analysis of such data is constantly evolving; see, e.g. [3, 5–11].

Progress in the fields of genetics and microbiology has opened up many fruitful avenues of research into the mechanistic causes of cancer [12]. The study of biomarkers such as DNA adducts [13] and other forms of DNA damage is of particular interest to many environmental scientists and also raises many challenging and interesting statistical questions.

Environmental Exposure Monitoring

The opinions expressed here are those of the author and do not reflect the opinions or policies of the United States Environmental Protection Agency. Mention of any trade names or commercial products does not constitute an endorsement or recommendation for their use.

Exposure monitoring has become increasingly important since the mid-1970s due to greater awareness about chemical pollution in the environment and concern about the role pollutants may play directly or indirectly in the early onset of disease (*see Environmental Hazard*). Drawing ingredients from environmental chemistry, epidemiology, industrial hygiene, and pharmacology, exposure monitoring is the means to estimate contact with environmental pollutants contained in air, water, food, products, and transport media. Table 1 shows the array of parameters and constituents that can be associated with exposure monitoring. Exposure monitoring is used in environmental health surveillance and is a key ingredient of the risk assessment process. In the former, exposure monitoring, sometimes including collection and analysis of biological media (blood, breath, feces, saliva, or urine), can provide an indication of a person's contact with one or more chemicals of interest (Figure 1). In this context, exposure monitoring is used to determine if chemical concentrations exceed allowable limits in specific media or to evaluate the trend of exposure to a chemical in the environment over time. This kind of trend analysis is frequently done to assess the efficacy of some effort or activity to reduce or eliminate emission of a chemical into the environment. In the latter, exposure monitoring information is used to construct an exposure assessment that links information about the inherent toxicity of a chemical (hazard assessment) and information about the quantity of the chemical that is capable of eliciting an adverse health response (dose-response assessment) to characterize public health risk to that chemical (Figure 2). In this context, exposure monitoring provides information (exposure assessment) about who is exposed, the route of chemical exposure (inhalation, ingestion, or contact), and the duration and frequency of contact with the chemical. This kind of information is used frequently to set limits

for chemical intake (allowable limits, tolerances) or to determine if additional intervention is warranted to mitigate risk to protect public health [1].

Classically, exposure is defined as the condition of a biological, chemical, or physical agent contacting the outer boundary of a human over time [3, 4]. In this context, contact can mean the visible exterior of the person at the skin or include openings into the body such as the mouth and the lungs. An agent entering the body can be described in two steps: contact (exposure) followed by crossing the boundary of the body (potential dose (PD)) with subsequent absorption, transport, and distribution of an amount of the agent to one or more sites in the body (internal dose) (see Figure 1). Thus, exposure monitoring measures the amount of an agent that an individual contacts over time in air, water, soil, food, a product, or a transport or carrier medium *via* inhalation, ingestion, or dermal absorption (*see What are Hazardous Materials?; Environmental Risks*).

Exposure over a period of time can be represented by a time-dependent profile of the exposure concentration. The area under the curve of this profile is the magnitude of the exposure, in concentration-time units [5, 6].

$$E = \int_{t_1}^{t_2} C(t) dt \quad (1)$$

where E is the magnitude of exposure, $C(t)$ is the exposure concentration as a function of time, and t is time, $t_2 - t_1$ being the exposure duration (ED). Integrated exposures are done typically for a single individual, a specific chemical, and a particular pathway or exposure route over a given time period. The integrated exposures for a number of different individuals (a population or population segment, for example) may then be displayed in a histogram or curve (usually, with integrated exposure increasing along the abscissa or x axis, and the number of individuals at that integrated exposure increasing along the ordinate or y axis). This histogram or curve is a presentation of an exposure distribution for that population or population segment (Figure 3).

Dose refers to the amount of an agent that crosses the external boundary of an individual. Dose is dependent upon the contaminant concentration and the rate of intake (ingestion or inhalation) or uptake (dermal absorption). PD is the amount of an agent that could be ingested, inhaled, or deposited on the skin. The absorbed dose is the amount of an agent

Table 1 Exposure monitoring parameters and constituents^(a)

Exposure parameter	Range of constituents
Agent	Biological, chemical, physical
Source categories	Anthropogenic/natural, area/point, stationary/mobile, indoor/outdoor
Media	Air, water, soil, sediment, dust, food, product, surface
Pathways	Inhalation, ingestion, skin contact
Duration	Seconds, minutes, hours, days, weeks, months, years
Frequency	Continuous, periodic, intermittent
Subjects	Individuals, groups, populations
Scope	Site specific, local, regional, national

^(a) Modified from reference [2]**Figure 1** Exposure monitoring, biological monitoring and their relationship to health surveillance, and risk assessment

absorbed into the body through the gastrointestinal tract, lungs, or skin. PD may be calculated as follows:

$$PD = C \times IR \quad (2)$$

where

PD: potential dose (mg day^{-1}); *C*: contaminant concentration in the media of interest (milligrams per square centimeter, mg cm^{-2} ; milligrams per cubic meter, mg m^{-3} ; milligrams per gram, mg g^{-1} ; or milligrams per liter, mg l^{-1}); and *IR*: intake or contact rate with that media per unit time (minutes, hours, days, weeks etc.). Frequently, PD rates are normalized to body weight as a function of time (e.g., milligrams per kilogram per day, $\text{mg}^{-1} \text{kg}^{-1} \text{day}^{-1}$) by multiplying by ED and frequency, and dividing by

**Figure 2** The risk assessment paradigm showing the role of exposure assessment in risk characterization and risk assessment

body weight and averaging time to yield an average daily dose. For example

$$I = \frac{(C \times CR \times EF \times ED)}{(BW \times AT)} \quad (3)$$

where

I: intake

C: concentration of the agent

CR: contact rate (ingestion, inhalation, and dermal contact)

EF: exposure frequency

ED: exposure duration

BW: body weight

AT: averaging time

More details and specific examples can be found elsewhere [4, 7].

Exposure monitoring can be performed by direct, indirect, or reconstructed methods. Direct exposure monitoring methods involve actual collection of microenvironmental or personal samples on the individual or in their proximity at the time contact with the agent occurs. Personal monitoring devices are used to collect air samples at the breathing zone or breath samples to measure inhalation of an agent. A duplicate portion of all food and beverages that is prepared and consumed is collected and analyzed to measure the agent in the diet. Areas of the skin are covered with an absorbent patch or are wiped

Figure 3 Hypothetical exposure distribution showing 90th percentile and individual with greatest exposure

with a solvent moistened gauze pad periodically to measure skin contact with the agent from a treated or contaminated surface. Additionally, there may be collection and analysis of biological samples (blood, breath, feces, saliva, or urine) from the individual being monitored to provide another measurement of exposure to the agent. These measurements are frequently combined with administration of an interview or questionnaire to capture information about the individual (age, gender, occupation, lifestyle, household size, housing characteristics) and the amount of time and frequency an individual spends performing a variety of tasks in different locations (time location activity patterns) during the monitoring period. This information is used to relate the monitoring measurements to contact with one or more agents and to determine if age, gender, socioeconomic level, and cultural, or lifestyle behavior may influence exposure to the agent being measured. This kind of information may provide an opportunity to associate an exposure to a specific age group (children or adults) or to specific activities (cleaning, food preparation, driving a car). These methods may be conducted for a single specific route of exposure (inhalation, ingestion, or contact) or for several routes to provide an aggregate estimate of exposure depending on the nature of the pollutant and the information desired. The strength of these approaches is that they measure exposure directly as it occurs by measuring the agent concentration at the interface of the person and the environment as a function of time, resulting in an exposure profile. Consequently these methods provide the most accurate estimate of exposure for the period of time of the measurements for the individuals being studied. They are capable of identifying major sources of exposure because they monitor individuals as they perform specific tasks or go about their normal daily routine throughout the day. They

can distinguish among various sources and pathways of pollution, which may be important for regulatory purposes and public health protection. They have the advantage of permitting selection of specific individuals for study such that monitoring can be conducted on individuals with specific personal characteristics (children in day care, females), socioeconomic characteristics (urban apartment dwellers, rural residents), or lifestyle (bicycle riders, gardeners, or sport fishermen) that may be pertinent to exposure to the agent. For example a study to estimate exposure of urban suburban and rural residents in an area to specific air pollutants would likely monitor selected air pollutants in the ambient environment, in indoor environments in the home and workplace, and in the modes of travel for the individuals being studied to obtain a complete picture of exposure to these air pollutants and to identify major pollutant sources (*see Air Pollution Risk*). A study of the contribution of local fish consumption to exposure to specific heavy metals such as mercury or organic pollutants such as *polychlorinated biphenyls* (*see Polychlorinated Biphenyls*) would likely focus on recreational fisherman who consume their catch regularly compared to residents who do not eat fish from local sources or who do not eat fish at all. In this case the study would recruit individuals with these dietary habits, investigate where fish were caught, how they were prepared and consumed, the quantity of any pollutants present in the edible portions, and the frequency of consumption to estimate the contribution of these fish to pollutant exposure. This kind of study might incorporate collection and analysis of biological samples in an effort to relate the amount of exposure measured to fish consumption. Direct exposure methods are limited by the fact that measurement devices and techniques do not exist for all agents and that assumptions must be made about relating short-term

monitoring measurements to estimates of long-term exposure. Generally, direct exposure monitoring is expensive, time consuming, and labor intensive to conduct. This is due to the requirements to select individuals with the characteristics of interest for study, collect, and analyze microenvironmental, personal, and biological samples, and record the time location activity pattern information to identify the sources of exposure for the individuals being studied. These methods have been used successfully to monitor individuals' exposure to volatile organic compounds, pesticides, particles, and heavy metals, and provide the best estimates of exposure to environmental agents [8–10].

Indirect exposure monitoring methods do not entail personal exposure monitoring. They combine environmental monitoring data or determinations about the concentration of an agent in various media in the environment with fate and transport models and assumptions about how contact with an agent takes place over time (scenario) to estimate the exposure that would occur to an individual engaged in that activity at that location for a specific period of time. As such exposure is estimated by combining estimates of the concentration of the agent in various media with assumptions about the time location activity patterns (scenario) of the individual where contact with the agent is expected to occur [4]. Using the air pollution example, ambient air monitoring network data for the pollutants of interest could be combined with a fate and transport model to estimate air pollution in the localities of interest. These estimates could be combined with assumptions about where and how individuals spend their time indoors with assumptions about the concentration of air pollutants in those microenvironments to construct an estimate of the exposure to individuals to these air pollutants. In the fish consumption example, residue levels in fish obtained from a local or regional survey could be combined with assumptions about preparation and consumption patterns to estimate dietary exposure to these compounds. The strength of the indirect methods is their economy, efficiency, and flexibility. Environmental monitoring data or concentration determinations are readily available or easily obtained for many agents in a variety of media. These data can be combined with fate and transport models for the appropriate pathways to construct reasonable estimates of exposure for specific scenarios or events.

The major weakness of these methods is the reasonableness of the estimates that are made about the concentrations of the agent in the environment at the point of contact of the individual generated by the fate and transport models and the assumptions about how the contact takes place over time that is described in the scenario to construct the exposure event. This is important because the further away the agent is measured from the point of contact with the individual the greater the uncertainty about the estimate of exposure in most cases. Likewise, care must be exercised in constructing the scenario in terms of the nature, duration, and frequency of the activity to correctly approximate time location activity patterns that would be monitored by direct exposure monitoring methods. Notwithstanding these limitations, indirect exposure monitoring methods are widely used to evaluate exposure to a variety of agents for regulatory purposes, estimate public health risk, or determine if additional exposure monitoring is needed to provide more detailed information about exposure to the agent.

Biological monitoring itself can be considered a form of direct exposure monitoring. But in this case, samples of biological media (blood, breath, feces, saliva, or urine) are collected and analyzed to measure the agent or its metabolites (biological markers). These measurements provide an indication of the amount of the agent that enters the body (dose). When this information is combined with information about time location activity patterns obtained from an interview or questionnaire, these measurements can be used to reconstruct the past exposure events that led to the measured agent or its metabolite in the body [4]. Thus, exposure reconstruction relies on measuring the agent or its metabolites in the body to back-calculate dose and exposure. Moreover, these methods can be used to provide information about the ability of the agent to exert a toxic effect at one or more target organs (target dose or target organ toxicity) when combined with physiological modeling, provided that sufficient information is known about the biological distribution and fate of the agent in the body. In the air pollution example, breath samples could be collected from individuals who would be administered a questionnaire about their recent time activity patterns and likely exposure to the air pollutants of interest. The breath sample analyses and questionnaire results would be evaluated to determine if the breath results could be related with

particular activities indicated in the questionnaire responses for specific air pollutants to indicate the source of exposure. Similarly, a series of blood samples could be collected from individuals who were reported to have recently consumed locally caught fish in an effort to estimate exposure to specific chemical residues from this source. The biological monitoring approach is useful because it provides an integrated estimate of exposure and does not require the measurement of individual routes of exposure. Moreover, it can provide information about the likelihood of the exposure to cause adverse health effects. Thus, biological monitoring may be more economical and efficient than direct personal exposure monitoring methods, provided that there is adequate information about time location activity patterns to relate the biological measurements to an exposure event. However, this approach is often limited to those agents that are not metabolized in the body or that have unique metabolites. Often metabolites lack specificity, which makes it difficult to assign them to a specific agent or to a specific exposure especially when the time–location activity pattern information is incomplete.

Environmental Hazard

Preliminaries to Environmental Hazard Analysis

Risk assessment has evolved in the past few decades as a rigorous quantitative approach with applications in numerous disciplines. In the fields of public health and environmental protection, for instance, the US National Academy of Sciences published its seminal “Red Book” [1] on risk assessment, in 1983. This influential work suggested a systematic, sequential process for researching risk, which included hazard evaluation as the first step. Since then environmental scientists have dealt with the concept of environmental hazard. After defining, evaluating, and ranking environmental hazards, more specific assessments of their risks have been developed. What is an environmental hazard? An environmental hazard is any condition, process or state that adversely affects the environment. Environmental hazards often manifest as physical or chemical pollution from unwanted waste or contamination usually due to economic activities of humans, such as mining, power generation, manufacturing, transportation, farming, forestry, and pesticide use in air, water, and soils (*see Air Pollution Risk; Water Pollution Risk; What are Hazardous Materials?*). Monitoring, remote sensing, and other techniques have shown that environmental hazards, singly or in combination, have affected and continue to impact the most remote places on earth. This ranges from ocean bottoms, threatening the oceans with extinction as living ecologic zones, up to the stratosphere, which has lost part of its screening capability of protecting humans, plants, and animals from the sun’s harsh ultraviolet rays.

Environmental hazards have potential for widespread harm to humans and the physical environment and appear to be increasing in number and extent. Today, global warming appears to be emerging as possibly the most dire and pervasive future environmental hazard. A few of the more common environmental hazards are reviewed briefly, below.

Lead

Lead is a ubiquitous environmental hazard. Its use historically was thought possibly to be injurious, but,

without scientific, epidemiologic methods, its actual risk could not be quantified (*see Lead*). Industries and consumers therefore disregarded the hazard and used lead in such products and processes involved in the manufacture of wine preservatives, coins, pewter, candle wicks, ceramic dishware, water pipes, paints, and, most significantly, as an additive in gasoline. Tetraethyl lead was found effective for increasing gasoline octane, and was prominently used in gasoline from the 1920s until the late 1980s. With gasoline lead residues in the streets, young children typically obtained doses in contaminated soil, or through ingestion of lead paint. Regulations now prohibit lead in gasoline or house paint.

PCBs

Industrial chemists synthesized a family of 209 simple molecules with marvelous properties as lubricants and heat absorbers. *Polychlorinated biphenyls* (PCBs) (*see Polychlorinated Biphenyls*) are virtually indestructible. After their introduction into commercial use [2], information began to emerge from environmental and occupational epidemiologic research, that PCBs caused chloracne, cancers, and other adverse health effects and were bioaccumulative and persistent. PCBs have been banned but since they are virtually indestructible they continue to circulate through the atmosphere, in river beds, soils, and the oceans, migrating up food chains to top predators such as the polar bear and man [3].

Asbestos

Asbestos was widely used as a flame retardant material and a component in automobile brake linings. Well after its established commercial use, scientists documented increases in lung disease among workers occupationally exposed to asbestos. Researchers eventually showed that asbestos exposure was causally associated with cancers of the lip, nasal passages, oral cavity, trachea, bronchus and lungs, mesothelial tissue, stomach, colon, and rectum (*see Asbestos*). Asbestos fibers – very thin, sinuous fibers akin to needles – are capable of migrating long distances within the body and lodging as foreign bodies. After this, the US Environmental Protection Agency banned the material and implemented a national program of remediation in schools and public buildings.

Environmental Health Risk

Risk is defined as the probability that a substance or situation will produce harm under specified conditions. Safety, the probability that harm or loss will not occur under specified conditions, is the reciprocal of risk. Both the risk and the safety are intimately associated with issues of perception [1]. Risk assessment is the process of estimating the potential impact of a chemical, physical, microbiological, or psychosocial hazard on a specified human population or ecological system under a specific set of conditions and for a certain timeframe [2].

Traditionally, risk has been assessed and managed by trial and error. Societies have survived natural disasters by building structures resistant to collapse under severe environmental conditions and exercising preventive measures to minimize diseases resulting from exposure to the environmental factors and contaminants. Risk assessment refers to the technical assessment of the nature and magnitude of the risks.

The complexity of the nature, interdependencies of environmental systems, and correlation between the hazard, exposure, and risk have resulted in development of the systematic approaches to risk assessment [3]. During the last decades, scientists, engineers, epidemiologists, among others, began conducting analyses of environmental systems, material, and technologies to understand risk and its relation to hazards, exposure conditions, and associated harms due to the exposure (*see, for example, Air Pollution Risk; Soil Contamination Risk*).

In the United States, efforts toward defining and managing risk properly have resulted in legislations that began in the 1970s with the formation of the regulatory frameworks, such as Environmental Protection Agency (EPA) and Occupational Safety and Health Administration (OSHA) in conjunction with other newly emerging industry of firms and academic centers [4].

Risk can be assessed with regards to safety (low probability, acute, high consequence, and accidental), human health (high probability, chronic, low consequence, and ongoing), ecology, public welfare, and goodwill. *Ecological risk assessment* (*see Ecological Risk Assessment*) considers indirect effects

of hazards on human health through disruption of the environment. The assessment of ecological risk follows the same steps as human risk assessment does. Public welfare and goodwill risks are value focused and are based on perceptions and property value concerns. Financial risk analysis focuses on the business viability, liability, insurance, and investment return [2, 3, 5].

Environmental Risk

Environmental factors can significantly impact human development, health, and welfare. Exposure to hazardous material in the air, water, soil, food, and physical hazards in the environment could result in unwanted morbidity and mortality. *Hazardous materials* (*see What are Hazardous Materials?*) impact humans and other organisms through multiple routes, including inhalation, ingestion, and dermal contact [3].

Environmental risk assessment is a scientific endeavor, which uses the facts and assumptions to estimate the potentials for adverse effects on human health, environment, and ecosystems from exposure to specific pollutants, toxic substances, and environmental hazards [6]. The process of risk assessment as used in public health and environmental settings is inherently a complex and highly technical process [7].

Risk must be determined both qualitatively and quantitatively from clarified facts and well-defined and accepted scientific approaches. Risk assessment provides a systematic scientific description of potential adverse effects from exposure to contaminants. The process should clearly define and describe hazards, exposure pathways, the nature of the adverse effects and their severity, uncertainties associated with data and their sources, as well as potentials for both the reversibility and preventability of risks [2, 7].

The anticipated risks posed by a specified problem or hazard needs to be expressed further in the context of multisource, multimedia, multichemical, and multirisk.

The cumulative risk assessment framework developed by the United States Environmental Protection Agency (USEPA) identifies procedure for the analysis, characterization, and possible quantification of the combined risks to health or the environment from multiple agents or stressors [2, 8].

Framework for Environmental Health Risk Assessment

Risk is determined from the concentration of the chemical or substances the person or the environment is exposed to, the rate of intake or dose, and toxicity of the chemical or substance [6]. Risk assessment uses either an engineering approach, focusing on the process control and safety, or toxicological approaches. A toxicological approach involves many assumptions and has limitations and uncertainties. Limitations of a toxicological approach are mainly related to the process uncertainties, difficulties associated with the correct estimate of the long-term, cumulative effects of low doses of toxins, and lack of sufficient and reliable data on the pathways and exposure levels [4].

The USEPA recommends a four-step procedure for assessing human health risk. The procedure consists of (1) hazard identification, (2) dose-response assessment, (3) exposure assessment, and (4) risk characterization [2].

As illustrated in Figure 1 the USEPA risk assessment procedure puts strong emphasis on the development of knowledge about the extent to which people are exposed to potentially harmful contaminants in their daily lives, level of the chemicals in the air, water, food, or other environmental media, the types of chemicals to which they are most often exposed, the source and levels of such exposures, the variability in exposures with time, and assumptions made about the mechanism and the rate of absorption of

the chemicals by the body. In order to eliminate the possibility of underestimating human risks, the procedure suggests a series of assumptions, preferably in a conservative range, about the chemical hazards, exposure scenarios, and the toxicological factors and constants [7].

An overview of the steps involved in the USEPA risk assessment procedure is presented.

Hazard Identification. Hazard is the inherent adverse effect that a chemical, process, or object poses with potentials for generating adverse consequences. Hazard both in its natural (geophysical and biological) and technological form can cause harms, such as human injury, illness, death, property damage, and ecological and environmental damage. Hazards identification is the quantitative measure of likelihood and severity of the harm [4, 9].

In terms of health risk assessment, hazard identification focuses on determining whether exposure to an agent can cause or increase a particular adverse health effect [9].

Hazard assessment calls for collection of scientific data on the characterization of the chemicals and hazards and the extent of contamination. Assessment evaluates both potentials for the release and types of contaminants. Since it is neither feasible nor cost effective to conduct risk assessment on all chemicals, hazard identification focuses on identifying chemicals of concern (COC) (*see What are Hazardous Materials?*). The common

Figure 1 EPA's four-step process for quantitative risk assessment

methods used to select COC involves comparing information obtained from environmental samples with (a) detection limits, (b) laboratory artifact based on blank data, (c) natural background, and the frequency, and (d) concentration-toxicity and chemical-specific screening criteria set by the regulations [10].

In quantifying human health risks, with respect to the toxicity, hazards can be characterized as carcinogens and noncarcinogens. Since risk assessment process is different for carcinogens and noncarcinogens, hazard identification also involves determining whether or not COC have the potential to increase the incidence of cancer in exposed humans. Principal evidence for such an analysis is obtained from human or epidemiologic, and long-term, controlled animal studies (*see Cancer Risk Evaluation from Animal Studies*).

Dose–Response and Toxicity Assessment. Dose–response is the quantitative relationship between the dose and effect caused due to the exposure. Toxicity assessment evaluates toxicity of a chemical from the laboratory data and dose–response curve (*see Dose–Response Analysis*), a graphical representation of the relationship between the degrees of exposure to a chemical substance and observed or predicted biological effects or responses [9].

Toxicological assessment based on animal studies and/or human epidemiology studies provides quantitative measures of chemical concentrations or doses above which carcinogenic potency or risk is expected. Examples include dose–response constants such as slope factors (SFs) expressed in units of $\text{mg}\cdot\text{kg}^{-1}\cdot\text{day}^{-1}$ for carcinogens, and reference dose (RfD) expressed in units of $\text{mg}\cdot\text{kg}^{-1}$ of body weight/day for evaluating risks of noncarcinogenic effects. SF is a plausible upper-bound estimate of the probability of an individual developing cancer as a result of lifetime exposure to a particular level of a potential carcinogen. These mathematical constants are determined by the upper 95% confidence limit of the slope of the linearized dose–response curves [10, 11].

The dose–response assessments are also used to determine carcinogenicity and the threshold levels for the COC. Carcinogens are identified according to the weight of evidence from human epidemiologic studies and data from laboratory experiments. Probable or possible carcinogens are further classified as A, B, C, and D [11]. Threshold is the lowest dose or exposure

of a chemical at which a specified measurable effect is observed and below which such effect is not observed [9].

The data obtained during the dose–response assessments are almost always taken from laboratory tests involving animals exposed to high levels of a substance for a relatively short period of time. Extrapolation using linear or curvilinear projections is then made to estimate the level of risk associated with the exposure to such chemicals for human populations. Owing to the limitations with the data and assumptions made to estimate toxicity constants, this process involves a large level of uncertainties [12]. Toxicity assessment process, therefore, also defines the types of uncertainty inherent in the estimates of mathematical constants and the ways these uncertainties could affect the estimated values for risk [11].

The USEPA suggests the use of direct methods to measure the exposure in order to minimize and/or eliminate uncertainties associated with the estimates from mathematical models commonly used in exposure studies, extrapolations from experiments involving animals [1], and measurements of the chemicals in the environment [7].

Exposure Assessment. Exposure assessment is the qualitative or quantitative estimation or the measurement of the dose or amount of a chemical to which potential receptors have been exposed or could potentially be exposed to. Exposure assessment defines the magnitude, frequency, duration, route, and extent of exposure to the chemicals or hazards of concern [9].

Exposure pathways are the course(s) a chemical or physical agent takes from a source to an exposed population or organism. The avenue by which an organism contacts a chemical, such as inhalation, ingestion, and dermal contact, are defined as exposure routes. Evaluation and quantification of exposure in a given situation requires data and a set of assumptions about the exposure scenarios, hazard resources, exposure pathways, type and levels of chemicals, and the potential receptors.

Exposure assessments generally focus on individual chemicals, media, and potential sources. It can be simple or complex depending on the needs and specifications of risk assessment. Exposure can be estimated from the direct measurements or application of models that involve a range of assumptions about the source, chemical properties, and receptor characteristics [13].

During the course of exposure assessment, general and sensitive populations in risk are identified along with the sources of contamination and potential scenarios for the exposure. Scenarios are the conditions under which the population may be potentially exposed to the contaminants. The spatial distribution of contaminants, potentials for environmental fate and transport are also assessed and short- and long-term exposures in terms of doses by exposure routes are estimated [11].

Exposure can be defined as acute, chronic, or sub-chronic. Chronic exposure is the long-term low-level exposure to chemicals, i.e., the repeated exposure or doses to a chemical over a long period of time (exposure that can last weeks to years). Acute exposure is a large exposure to a chemical or dose over a short period of time (exposure for minutes to hours with some exceptions that allow acute exposures to encompass up to 3 months).

Subchronic exposure is defined as a short-term, high-level exposure to chemicals i.e., the maximum exposure or doses to a chemical over a portion of a lifetime (exposure that lasts days to weeks) [9, 10].

Mathematically (equations (1) and (2)), exposure can be estimated from the average concentration of the chemicals and the duration of exposure [14]:

$$E = \int_{t_1}^{t_2} C(t) dt \quad (1)$$

$$E = C \cdot \Delta t \quad (2)$$

where E is the exposure, C is the average chemical concentration (chemical concentration at the point of contact), and Δt is the duration of exposure. Exposure concentrations are typically expressed in units such as $\mu\text{g}\cdot\text{M}^{-3}$, $\text{mg}\cdot\text{m}^{-3}$, $\text{mg}\cdot\text{kg}^{-1}$, $\mu\text{g}\cdot\text{l}^{-1}$, or $\text{mg}\cdot\text{l}^{-1}$.

In different microenvironments (j), the exposure to any chemical i can be simply estimated from the filed information using equations (3a and b):

$$E_{j,k} = C_{j,k} \cdot \Delta t_{j,k} \quad (3a)$$

$$E_{i,j,k} = C_{i,j,k} \cdot \Delta t_{i,j,k} \quad (3b)$$

Where $E_{j,k}$ is the exposure of target person k to a given pollutant during the time interval Δt , and $C_{j,k}$ is the average concentration to which person k is exposed during the time interval Δt and in microenvironment j . The term $\Delta t_{j,k}$ represents the time spent by person k in microenvironment j [14].

For acute health effect Δt is a short interval that reflects the peak concentration for an effect. This equation can be expanded to multiple pollutants where the receptor (k th person) is exposed to a concentration of the i th chemical contaminant in the j th microenvironment ($C_{i,j}$). This concentration is constant during the interval $\Delta t_{j,k}$. The time integrated exposure or total exposure, E^T , can be also calculated for the exposure of the k th person (equation (4)) or total population ($k \rightarrow K$ from equation (5)) to the i th contaminant, over the possible microenvironments ($j \rightarrow J$):

$$E_{i,k}^T = \sum_j C_{i,j} \cdot \Delta t_{j,k} \quad (4)$$

$$E_{i,k}^T = \sum_k C_{i,j} \cdot \Delta t_{j,k} \quad (5)$$

Equation (6) assists estimation of a time-environmental integrated population exposure to a single contaminant for a population of persons and a series of microenvironments:

$$E_i^T = \sum_j \sum_k C_{i,j} \cdot \Delta t_{j,k} \quad (6)$$

The population averaged exposure (intake) of a chemical *via* an exposure pathway in units of $\text{mg}\cdot\text{kg}^{-1}\cdot\text{day}^{-1}$ can be estimated as follows:

$$I = C \cdot \left(\frac{CR}{BW} \right) \cdot FI \cdot \frac{EFD}{AT} \quad (7)$$

In this equation, C is the chemical concentration in the exposure medium, CR is the rate of chemical in medium contacted, BW is the body weight (average over exposure period), FI is the fractional intake from the exposure, EFD is exposure duration, and AT is the averaging time [14].

Risk Characterization. Risk characterization is a quantitative estimate of risks for the assumed exposure scenarios (source, chemicals, pathways, and receptor). During the risk characterization step, risk is estimated for the most probable exposed population and for the maximally exposed individuals. For example, carcinogenic risk is estimated by multiplying the estimated chronic daily intake dose (I_C) during the

exposure assessment by the value of SF from toxicity assessment:

$$\text{Risk} = I_C \times SF \quad (8)$$

The noncarcinogenic risk is normally characterized in terms of hazard index, which is calculated as the ratio of the estimated chronic daily intake of concentration (I_N) from exposure studies to the reference concentration (RfC):

$$HI = \frac{I_N}{RfC} \quad (9a)$$

$$HI = \frac{\text{Concentration}}{RfC}$$

$$HI = \frac{\text{Dose}}{RfD} \quad (9b)$$

Hazard index is a standard unit for quantifying noncarcinogenic risk. Noncarcinogens exhibit a threshold effect such as RfC and RfD below which they do not cause adverse health effects [11, 14]. An index greater than 1.0 indicates the possibility of an adverse health effect due to exposure.

Risk characterization can also identify all potential sources and their impact on the estimated risks, along with their relative positioning and distribution in relation to other risks to the community. Risk characterization addresses the hazard and the exposure, the nature and likelihood of the health risk; individuals or groups at risk; the likelihood and magnitude of risks; and the severity anticipated for the adverse impacts or effects. This step also involves evaluation and characterization of the scientific evidence supporting the conclusions about the risk with respect to their strength, accuracy, and uncertainty [14]. Risk characterization is also used to evaluate weather besides adverse effects on the health or the environment, if risk can impact social or cultural consequences [2].

Sources and Methods of Capturing Data

The quantitative risk assessment is a data-intensive process that requires collection of reliable data and selection of methodologies and models that matches the need of the risk assessment. Risk models commonly assume different scenarios for the source terms, and use equations and thermophysical

properties for the chemicals in question. The performance of the methods and risk models, however, needs to be characterized and verified in order to ensure their integrity and reliability. Evaluation and validation might include sensitivity testing for evaluating parameters with the greatest influence on the model output, model accuracy, precision, and predictive power [3, 15].

The principal methods of data collection for risk assessment programs include, but are not limited to, environmental sampling; laboratory studies; review of the historical data; analysis of the process, sources and the receptors; review and analysis of the chemical data; and assessment of the environmental parameters and potentials for chemicals fate and transport [3]. The success of environmental sampling programs depends on the proper sampling and analysis plans and consideration of a variety of factors in selecting sample locations and analytical detection limits. These programs must demonstrate clear methodologies for data collection, data verification, and evaluation of the accuracy and conservativeness of the risk analysis [10].

Data from both field observations and laboratory studies in controlled settings can be used in the risk modeling process. Laboratory and environmental (field) tests can provide strong evidence linking a chemical to observed adverse effects. Since laboratory data tends to be less variable than those from the field studies, responses may differ from those observed in the environment. Field studies, however, have potentials to provide environmental realism that laboratory studies lack [16].

Environmental data can also be obtained from data files or organizations that perform sampling, analysis, and data validation. Owing to the variable nature of the sampling and analysis, data is commonly screened and evaluated prior to being utilized in the risk assessment models. Toxicity values such as RfDs, RfCs, and SF can be estimated from independent research or received from the USEPA approved sources such as integrated risk information system (IRIS) [17]. The IRIS is an electronic database containing information on human health effects that may result from exposure to various chemicals in the environment. The system is a collection of computer files, which contain descriptive and quantitative information on oral RfDs and inhalation RfCs for chronic noncarcinogenic health effects and hazard identification, oral SF,

and oral and inhalation unit risks for carcinogenic effects [17, 18].

Since data could be incomplete or vary depending on the source of information, particularly in the areas of toxicity and human errors, an expert opinion is necessary to assess the existing data and their suitability for a quantitative risk analysis.

Risk Management

Environmental risk analysis involves both risk assessment and management of natural and technological hazards. Risk assessment refers to the technical assessment of the nature and magnitude of risks. Risk management, however, is the process of evaluating and selecting appropriate responses for mitigating risk and the consequences [4].

Risk assessment is used to determine health guidance values for environmental hazards. It is also used to establish regulatory exposure standards to adequately protect public health and the environment. Risk management, however, is the process of weighing policy alternatives and selecting the most appropriate action through integrating results of risk assessment with social, economic, and political concerns [1, 4]. Risk management often involves the public; it requires examination of the term *acceptable risks* and the perception of the assessed risks [11] (see **Risk and the Media; Stakeholder Participation in Risk Management Decision Making**).

Having characterized the risk and the degree of uncertainty associated with the risk, the best decisions must be made in order to eliminate and/or mitigate the risks. Effective risk management must include the stakeholder perceptions of risk and any other social or cultural impacts associated with risks posed by a specified problem and/or hazards [2].

Integration of the stakeholder perceptions of the risks with scientific and contextual aspects of the risks to human health or the environment assists policymakers with development of guidelines for effective risk management and mitigation.

Risk Communication

Risk communication is the continental exchange of information about health and environmental risks among risk assessors, risk managers, the public, the media, interested groups, and others. It is

possible to arrive at a meaningful idea of success for risk communication by considering a broad public purpose that successful risk communication serves [19].

Environmental Health Risk Assessment

General Considerations

Quantitative health risk assessment is a tool for making predictions about the impact of substances in the environment on health. Despite the use of scientific principles and a reliance on the most appropriate data from the scientific literature, risk assessment, in the strict sense of the word, is not, by itself, a science. This is because the predictions of risk and/or safety that derive from a risk assessment are rarely verifiable. This is the case because the risks that are generally addressed are at, or just above, the *de minimis* level. That is, risk assessments are generally carried out in order to specify a level of acceptable environmental exposure that poses little or no significant elevation of risk. The residual risk remaining after risk-based controls are put in place should, therefore, rarely be measurable above background levels. Risks that are identified through a risk assessment process as having the potential to pose more than a *de minimis* level of risk are generally reduced without waiting for statistically verifiable evidence of impacts on public health. When environmental conditions are such that they result in observable and quantifiable levels of an adverse health effect in a population (as opposed to predicted or potential levels of effect), then the prediction of risk through the application of formal risk assessment is largely superfluous. Furthermore, nearly all health effects known to result from exposure to environmental contaminants are multifactorial in origin, and can occur from genetic and lifestyle factors in the absence of significant exposure to environmental contaminants. Thus, in many cases, the increase in the incidence of a given disease resulting from an environmental exposure that may be predicted from a risk assessment is within the confidence limits of the background incidence of that disease in the population. Health risk assessment is, therefore, a predictive tool rather than an experimental or even an observational science. In practice, risk assessment is used both to predict the inherent risk (or safety) associated with a substance (e.g., what is the risk associated with a unit exposure to benzene? what is the safe dose of methyl mercury?), and to describe the risk associated with a given scenario (e.g., what

is the risk from drinking water containing $x \mu\text{g l}^{-1}$ of arsenic?) (see **Water Pollution Risk**).

Despite more than 50 years of the practice of environmental health risk assessment, its practice and application continue to provoke controversy. On a fundamental level, the notion of quantitative risk is not well understood by the public (see **Role of Risk Communication in a Comprehensive Risk Management Approach; Risk and the Media**), and so the results of risk assessments are often misinterpreted and misused. This is compounded by the fact that risk assessment is a highly interdisciplinary practice. The synthesis of an overall assessment of risk across disciplines in the face of multiple uncertainties makes the communication of the findings and their implications difficult. Furthermore, as a tool to inform regulatory decision making, risk assessment is used by different agencies and groups with differing agendas. This can lead to controversy over its proper goals and application and thus there is often no obvious consensus as to what the appropriate goal of a risk assessment should be. In addition, the use of risk assessment for standard setting and environmental regulation is seen by some as reflecting a willingness to accept environmental risk (see **Environmental Hazard**). For those with such a viewpoint, the precautionary principle is often cited as a more appropriate and uncompromising alternative. The two approaches, however, are not necessarily incompatible, and there are situations such as those requiring risk–benefit balancing (e.g., consumption of moderately contaminated fish) where there is no obvious role for the precautionary approach. Just as there are those for whom environmental health risk assessment is, by its nature, insufficiently protective, there are those, often in the regulated community, for whom it is unnecessarily conservative (i.e., protective). This point of view arises in response to the various conservative default assumptions in much of the risk assessments carried out by governmental agencies. To a large extent, these conservative assumptions are intentional and represent a public health protective response to the uncertainty inherent in many steps in the risk assessment process. Nonetheless, the proliferation of such assumptions can result in an unintended level of conservatism in the overall assessment. This has led to several approaches that attempt to restrict the level of conservatism within intended bounds (see below).

Two different forms of quantitative risk assessment are practiced, often by the same governmental agencies, and interested groups that seek to influence the policies and decisions of those agencies. These two different forms have somewhat different orientations and address different regulatory and communication goals. One form of risk assessment can be referred to as *safety assessment*. This type of assessment seeks to identify the largest level of exposure or dose that can be reasonably expected to be without adverse effect. Safety assessment does not necessarily provide quantitative information on the risk associated with exposure above this “safe” level. In the United States, such assessments are most commonly applied to substances judged to be noncarcinogenic, or to the noncarcinogenic effects of carcinogens (*see Environmental Carcinogenesis Risk*). The rationale for this application is based on the long-standing notion that, for most types of noncancer toxicity, there is a dose (the threshold dose) below which no significant adverse effects will be experienced even over a lifetime of exposure (*see Threshold Models*). In the United States, the most common examples of safety assessment are the United States Environmental Protection Agency’s (US EPA’s) reference dose (RfD) for oral exposure or reference concentration (RfC) for inhalation exposure. The RfD is defined as “an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime” [1]. The RfC is similarly defined as “an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime” [2, 3]. The RfD is expressed in units of dose (e.g., milligrams of substance per kilogram body weight per day), while the RfC is expressed in units of concentration in air (e.g., milligrams of substance per cubic meter of air). In some other countries, particularly in Europe, this type of assessment is also applied to carcinogens. More recently, the notion of a sharp threshold for adverse effects has been challenged by the recognition of variability in response within human populations as well as the apparent continuous effect of some toxicants through the lowest doses observable (e.g., the neurodevelopmental effects of gestational lead exposure). The population

variability in response is best seen in epidemiological studies when dose (or exposure) response data (*see Dose–Response Analysis*) are viewed without grouping into arbitrary exposure categories. In contrast to the much neater collection of observations generated in classical animal toxicology studies, such dose–response data typically appear as a point cloud. A good example of this is the data on the association of neurodevelopmental test scores with gestational methyl mercury exposure [4]. Both the variability in response and the continuous dose–response can make the notion of identifying a clear threshold for adverse effects a practical impossibility.

The other type of risk assessment seeks to quantify the risk associated with any exposure or dose of an environmental agent. In the United States, this form of risk assessment is generally applied to carcinogens. The most common example of this type of assessment is the cancer potency slope, which (as employed by the US EPA) gives the probability of developing a dose-related tumor for a unit dose (e.g., per milligram of carcinogen per kilogram body weight per day). Historically, in contrast to the threshold assumption applied to noncancer safety assessment, cancer risk has been assumed to be linear and to have no threshold (i.e., the risk is assumed to be zero only at zero dose). This assumption was based on the idea that a heritable genetic change in the DNA is a necessary causative step in carcinogenesis and that, in principle, one molecule of a carcinogen has a small but finite chance of causing such a change (*see Gene–Environment Interaction*). The most recent version of the US EPA’s Guidelines for Carcinogen Risk Assessment [5] still employs a linear no-threshold approach as the default assumption (although linearity is assumed only between the origin and a “point of departure” defined by the observable dose–response data) for chemicals, for which the mode of action of carcinogenesis is not known, and for carcinogens with an established mutagenic mode of action. However, for carcinogens with clearly defined modes of action that lead to nonlinear dose–response models and/or dose–response models with quantifiable thresholds, cancer risk may be based on threshold and/or nonlinear models rather than on the linear assumption. In practice, given the evidence required to establish a specific mode of action, departures from the linear, no-threshold assumption are still rare. A notable recent exception to this is chloroform. On the basis of a detailed mode of action

information indicating that the primary mechanism for the carcinogenicity of chloroform is based on cell lethality and regenerative hyperplasia, the US EPA has addressed the carcinogenicity of chloroform through the same noncancer (safety assessment) risk assessment approach used to derive the RfD that is, by itself, intended to be protective against chloroform-induced cell lethality [6].

It has been recognized for some time that the distinction between the determination of noncancer risk through safety assessment and cancer risk through a continuous dose–risk relationship is largely artificial and an artifact of the history of the development of risk assessment. Movement toward a unified cancer/noncancer risk assessment framework (sometimes referred to as *harmonization*), however, has been slow. In part, this is because various risk-based regulatory policies have been developed with specific reference to one or the other risk assessment approach. The US EPA's recent approach to risk assessment for chloroform, applying a safety assessment approach to protect against noncancer effects that occur “upstream” of tumor production, is an important step in the direction of reconciling these two approaches.

Another controversial aspect of health risk assessment is that health risk can include a very broad range of effects – from mild irritation to lethality. Not all risks are of equal severity or concern (even if they occur at the same dose); therefore, risk is a function both of the likelihood of occurrence and of severity. It has proven difficult to arrive at a common metric of severity. For example, while it may be readily agreed that progressive kidney dysfunction is a more severe outcome than mild, transient neurological effects, it is not clear in objective quantitative terms how much more severe an outcome it is. For these reasons, environmental health risk assessment is, in practice, defined either as the process of estimating the probability of a given adverse outcome (most usually cancer) at a given dose or as the determination of the largest dose that will not result in *any significant* adverse outcome. It is generally acknowledged that some effects may be adverse, but insufficiently significant from a public health standpoint to support guidelines or standards. The issue of what constitutes a “significant” adverse outcome is somewhat subjective. In practice, even effects that do not, strictly speaking, impair health, such as mild dental mottling or skin discoloration,

have formed the basis for risk-based standards and guidelines. Mild transient health effects (e.g., mild skin irritation or itching), on the other hand, have generally not been considered “significant” adverse effects.

One of the major limitations of environmental health risk assessment that has only recently begun to be fully appreciated is the fact that historically, this tool was developed to address the risk associated with exposure to individual substances. Humans, however, exist in an ocean of stressors with a myriad of exposures occurring at any point in time. Given ubiquitous coexposures, the risk from coexposures to a specific substance may be significantly greater or less than that calculated on a single substance basis. While some combinations of exposures are known to result in additive or synergistic risks (e.g., smoking and asbestos) there are few data that are useful for estimating the risk from even common combinations of different environmental substances. For some closely related chemicals with common mechanisms of toxicity, however, metrics of relative potency (toxic equivalency factors or TEFs and relative potency factors or RPFs) have been developed that express the overall potency of a mixture in terms of an equivalent concentration or dose of the most potent constituent. TEFs have been developed for PCDDs (polychlorinated dibenzo-dioxins), and related PCDFs (polychlorinated dibenzo-furans) and coplanar PCBs (polychlorinated biphenyls) relative to 2,3,7,8-TCDD (tetrachlorodibenzo-p-dioxin) [7], and also for carcinogenic PAHs (polycyclic aromatic hydrocarbons) relative to benzo-*a*-pyrene [8]. RPFs have been developed for organophosphate pesticides [9]. Various approaches have been suggested for estimating cumulative risk from chemicals that are less closely related structurally or through their mechanisms [10], but not surprisingly, given the range of possible interactions, progress in this area has been slow (*see What are Hazardous Materials?; Environmental Risks*).

Despite uncertainties, limitations, and various areas of controversy, quantitative health risk assessment is an essential tool for the setting and carrying out of environmental policy. It provides a scientifically based and practical, if imperfect, metric for setting regulatory policy for the protection of public health, for prioritizing environmental action, and for comparing risks.

The Structure of Health Risk Assessments

Since its publication in 1983, the US National Research Council's report, *Risk Assessment in the Federal Government: Managing the Process* (often referred to as the *Red Book*) has defined the structure of a formal health risk assessment [11]. This structure includes four key steps: hazard identification, dose–response assessment, exposure assessment, and risk characterization. Each of these steps is discussed in more detail.

Hazard Identification

In this step (sometimes referred to as *hazard assessment*), both the substances (or more generally, the stressor) in question and the health endpoints resulting from exposure to the substance are determined and documented. The identification of the substance in question is not necessarily a trivial matter. Chemicals may be complex and variable mixtures of related molecules. PCBs (see **Polychlorinated Biphenyls**) and PCDDs, for instance, include many different congeners, each with different numbers and arrangements of chlorine atoms. Each congener and each mixture of congeners may have qualitatively and quantitatively different potencies. Metals, such as mercury (see **Methylmercury**), arsenic (see **Arsenic**), chromium (see **Hexavalent Chromium**), and nickel can have different valence states each of which can form different compounds that differ markedly in their toxicological properties. In addition, even well-characterized compounds may commonly contain chemical impurities that, themselves, have toxicological properties. Care must be taken in specifying, as precisely as possible, the substance or mixture that is under study. Although sometimes overlooked, equal care must be taken in not applying risk assessments to exposures that do not clearly correspond to the specific substance addressed in the assessment.

Hazard identification should reflect a thorough review of the relevant scientific literature for the substance. In addition to toxicologic studies *per se*, this can also include pharmaceutical/pharmacological studies, medical studies, and nutritional studies. The review should focus on the absence of adverse effects as well as on their occurrence. Studies should be evaluated for their overall quality, their physiological and toxicological relevance to humans (e.g., does an effect observed in an animal study reflect a

toxicological mechanism that is likely to be present in humans?), their relevance to potential human routes of exposure (e.g., are toxicological findings from an inhalation study relevant to risk from ingestion?), and their ability to support quantitative dose–response assessment. Studies that cannot support quantitative dose–response assessment can still be qualitatively useful in supporting the relevance of other studies. This review of the scientific literature results in the identification of a key study or of several closely related studies. In addition, the review should identify and describe, if possible, a mode of action for the critical effect. The mode of action describes the key steps leading to the critical effect, but is a less precise description than a formal toxicological mechanism at the molecular level. In addition to assisting in the evaluation of the critical effect in terms of its relevance to humans and its potential to progress to more severe effects, identification of a mode of action can influence the nature of the dose–response analysis for carcinogens under the current US EPA's Guidelines for Carcinogen Risk Assessment [5] (see above).

Generally, in hazard identification, a single health endpoint (the critical effect) is chosen from the key study as the basis for the dose–response and exposure assessments that follow. As a general rule, the critical effect is the most sensitive adverse health outcome, i.e., the significant health effect that occurs with the lowest dose. Judgment must, however, be exercised in this selection, since the most sensitive endpoint may be of doubtful health significance (e.g., enzyme induction, minimal organ weight gain, or minimum whole body weight loss), may not be well documented, and/or may not have sufficient quantitative data to support dose–response assessment. For example, in its 2000 report, the US National Research Council on the toxicology of *methyl mercury* identified cardiovascular effects as possibly the most sensitive health endpoint, but chose neurodevelopmental effects as the critical effect, because they were more extensively studied and documented [4]. Approaches for combining several health endpoints of varying severity have been proposed [12], but have not been used for the formal derivation of guidelines and standards.

Dose–Response Assessment

The overall goal of the dose–response assessment is to derive a generalizable quantitative relationship between the dose (or exposure) and the occurrence

or risk of the critical effect identified in the hazard identification step. A good general discussion of the dose–response process is given in the online background information to the US EPA’s Integrated Risk Information System (IRIS) (<http://www.epa.gov/ngispgm3/iris/rfd.htm>). Given the historical dichotomy between the cancer and noncancer risk assessment approaches, the specific goals of dose–response assessment for each type of assessment have been fundamentally different. For cancer risk assessment, the goal of *dose–response analysis* has been to estimate the risk at any given dose through the fitting of a dose–response model to the empirical data. In practice, the cancer dose–response data have largely been animal chronic bioassay data, in which the doses have been far in excess of human environmental doses, and the response rates have been far in excess of those that are appropriate for setting standards and guidelines for protection of public health (see **Cancer Risk Evaluation from Animal Studies**). The observed response rates of tumors in animal tests is generally in the whole number percentage range, while standards and guidelines are generally set on the basis of risks in the 1×10^{-4} to 1×10^{-6} range. This means that mathematical dose–response models are fit to the observed data in the very high-dose range, and extrapolated downward across 3–5 orders of magnitude to the very low dose range where little information on the nature of the dose–response relationship exists. Estimates of cancer risk are thus often driven more by generic assumptions about the type of dose–response model that is applied than by the empirical toxicological data. On account of large uncertainties about the shape of the dose–response curve in the (low) dose range of interest, and because of a general lack of information about the mechanisms underlying carcinogenicity in the low-dose range, standards and guidelines for carcinogens have traditionally been based on an admittedly conservative, linear, no-threshold dose–response model. Only recently has the US EPA begun to entertain the use of nonlinear and threshold dose–response models [5] (see above).

When human epidemiological data on cancer incidence and exposure data in a well-defined cohort are available, such uncertainties can be reduced, although the observed risks must be sufficiently large to be detectable and statistically meaningful, given the available cohort size, exposure range, and background incidence of the cancer in the population.

The exposures (doses) encountered in epidemiologic studies, although often originating from relatively contaminated occupational environments, are, by definition, within the range of human exposures. Thus, when epidemiological data are used as the basis for cancer dose–response assessment, the uncertainties generally originate less from issues of the selection of the dose–response model or high-dose to low-dose extrapolation than from considerations of study power and exposure misclassification.

As with cancer risk assessment, much of the data for noncancer (safety) risk assessment derives from animal studies. In noncancer risk assessment, the goal has been the assessment of a safe dose rather than a determination of the risk at any given dose. This has led to an approach to dose–response assessment that has, until recently, concentrated on the lowest portion of the dose–response curve to the virtual exclusion of the information contained in the remainder of the curve. In this approach, the largest dose at which there is no significant increase in the incidence of an adverse effect above the background incidence is defined as the no observed adverse effect level (NOAEL) dose [1]. When no such dose can be identified, the smallest dose at which a statistically significant increase in the incidence of an adverse effect is observed (the lowest observed adverse effect level or LOAEL) is identified. The NOAEL or LOAEL then becomes the point of departure for setting the virtually “safe” dose. The possible values that the NOAEL or LOAEL can assume are limited to the experimental doses (or in an epidemiological study with grouped data, the arbitrary exposure groupings). The NOAEL is thus dependent on the size of the study (i.e., the number of dose groups) and on the range and spacing of the doses in the original study. NOAELs (and LOAELs) for the same or different substances derived from different studies are, therefore, not easily comparable. The shape and slope of the overall dose–response relationship is largely irrelevant in this approach and much potentially useful information remains unused. Furthermore, since NOAELs and LOAELs can only be derived from epidemiologic data that have been binned into discrete dose or exposure categories, this approach also requires loss of valuable information when applied to epidemiologic data derived from studies with continuous measures of exposure or dose.

During the last two decades, the *benchmark dose estimation* (see **Benchmark Dose Estimation**)

approach has gradually gained acceptance as an alternative in dose–response analysis [13–15]. Initially, the benchmark dose approach was applied to noncancer risk assessment, and more recently, to cancer risk assessment for identifying a point of departure in linear extrapolation [5]. In this approach, a dose–response model is fitted to the empirical data, and the probability of a small but observable response (e.g., 1%, 10%) is chosen. The lower confidence limit on the dose corresponding to that probability is then identified as the *point of departure* for setting the virtually “safe” dose (e.g., an RfD). The original intent of such a point of departure was to provide a generalizable (i.e., study-independent) estimate of the NOAEL. However, it is clear that such a value is not conceptually equivalent to the NOAEL. In part, this is because the NOAEL is, by definition, study-dependent, and therefore, the notion of a generalized NOAEL is not clearly defined. This is also the case because the benchmark dose is, by definition, not a no-effect level; rather, it is a lower bound estimate of the dose corresponding to a 1, 5, 10%, etc. effect level. Various uncertainties in the application and interpretation of this approach still need to be resolved. Among these is the fact that, in most cases, the dose–response functions applied to the observed data are chosen from among a standard set of functions (e.g., Weibull, gamma, logistic) identified on the basis of their mathematical utility. The particular mathematical function ultimately used to derive the benchmark dose is generally chosen on the basis of its suitability to the data rather than on the basis of its underlying biological plausibility. Additionally, as discussed above, the public health interpretation of the benchmark dose remains uncertain.

Efforts have been underway for at least two decades to harmonize cancer and noncancer dose–response assessment [16]. This effort is complicated, however, by the fact that cancer and noncancer dose–response assessments tend to have data on opposite extremes of the dose–response curve as their starting points. While, for reasons of practicality in study design, cancer dose–response often starts from unrealistically high doses, noncancer dose–response seeks to identify doses spanning the threshold for response.

One approach that has received considerable attention involves the identification of noncancer endpoints for carcinogens. This approach is exemplified by US EPA’s recent treatment of chloroform

as discussed above [6]. Such effects (enzyme induction, hyperplasia, DNA adduct formation, mutagenesis, etc.), which may be predictive of eventual tumor formation, can then be modeled using noncancer dose–response techniques such as the benchmark dose [15]. Such an approach holds promise but raises questions about the extent to which such responses are necessarily adverse and truly predictive of carcinogenicity. Such approaches cannot be generalized to all carcinogens and will likely find application on a case-by-case basis. A more broad-based approach to harmonization of cancer and noncancer dose–response does not appear likely in the foreseeable future.

Exposure Assessment

The role of the exposure assessment portion of environmental health risk assessments depends on the purpose and application of the risk assessment. In predictive risk assessments, the purpose of the assessment is to predict the risk that will occur under a future or hypothetical set of exposure conditions. Examples of predictive risk assessments are those intended to set generic acceptable levels of a contaminant in drinking water and those intended to set generic acceptable levels of contaminants in soil. Since these exposures are not occurring in the present, they cannot be measured, and so must be predicted under a specific exposure scenario. In such cases, the exposure assessment is required to quantitatively characterize those aspects of the scenario that determine the dose. This is generally accomplished with a model that integrates the dose over time to predict the cumulative dose. Such models require identification of the relevant routes of exposure (ingestion, inhalation, dermal absorption), the receptors (children, adults, workers, pregnant women, etc.), the concentration of the contaminant in the relevant media (soil, air, water, and food), the uptake or intake rate for each medium (e.g., grams of soil ingested per day, cubic meters of air inhaled per day, liters of water ingested per day), the frequency of exposure (continuous, daily, monthly, etc.), the duration of exposure (lifetime, childhood, occupational lifetime, single day, gestation, etc.), and factors such as the bioavailability of the substance in the particular medium that can alter the nominal dose [17]. Such scenarios, even when realistic, are often based on assumed or hypothetical populations with typical activity patterns. Generic parameters for common

activities associated with environmental exposures can be found in the US EPA's Exposure Factors Handbook [18]. In contrast, descriptive risk assessments seek to describe the ongoing risk from measurable exposures in an actual setting. Examples of descriptive risk assessments are those intended to characterize workplace risks and those describing the risk to consumers of specific species of contaminated fish from a specific water body. Although the exposures in such cases are theoretically measurable on a real-time and individual basis, it is more common for exposures to be characterized by temporally and geographically discrete sampling of the environment or by using generic exposure assumptions such as the ones discussed above. Characterizing the exposure of specific populations obviously requires more effort, is more data intensive, and is more expensive than applying generic exposure assumptions. Thus, even when exposures are ongoing, descriptive risk assessments tend to rely on such generic assumptions.

When generic exposure assumptions are used, point estimates (single numerical values) have traditionally been assigned to each exposure variable (e.g., the volume of daily water consumption). Recognizing, however, that each variable can assume a range of possible values, attempts have been made to select upper percentiles for exposure variables so as to be inclusive of most of the potentially exposed population. Such values can often be located in the US EPA's Exposure Factors Handbook [18]. When dealing with the suite of exposure variables in an exposure model, however, the mathematical combination of upper percentile values in the exposure model can quickly compound into an extreme upper percentile estimate of the overall exposure. This has been referred to as *redundant* or *compounding conservatism* [19, 20]. Various combinations of central tendency estimates and upper percentiles have been proposed to remedy this situation [21], but such approaches are necessarily arbitrary, and result in exposure estimates with an unknown degree of population inclusiveness. These problems arise because no single value can adequately represent variables that are, in fact, distributed quantities. Over the last decade, probabilistic (largely Monte Carlo) approaches have been proposed to address the underlying variability and uncertainty in exposure assessment [22, 23]. Such approaches allow for realistic descriptions of the full range of exposure variables and yield a distributional description

of the integrated exposure estimate. This distributional description of the overall exposure estimate allows risk managers to select the exposure and related risk at a specific percentile of the estimated population distribution (e.g., 90th, 95th, 99th upper percentile of exposure) for a given exposure scenario. Probabilistic approaches, therefore, hold the potential for more realistic (if still generic) exposure assessment. The acceptance of such approaches has, however, been slow among regulatory agencies. In part, this is because the probabilistic description of many key exposure parameters is uncertain. This uncertainty stems from the lack of information about the specifics of distributions, particularly in their extreme values. Another factor in the slow progress in using probabilistic approaches is that differences among populations, including regional and ethnic differences, make the derivation of generic distributions difficult since different populations may not lie on the same continuous distribution. In principle, probabilistic approaches are also applicable in dose-response assessment. However, uncertainty regarding the probabilistic description of several key aspects of dose-response extrapolation (e.g., animal-to-human, subchronic-to-chronic, LOAEL-to-NOAEL) as well as the general lack of data on interindividual human variability in dose-response have traditionally limited probabilistic approaches to the exposure assessment portion of risk assessments (see **Low-Dose Extrapolation**).

When risk assessments are conducted to characterize the inherent risk associated with a substance (rather than to characterize a specific exposure scenario), the role of exposure assessment is to relate the toxicokinetics underlying the key dose-response study or studies to the conditions of human exposure that may ultimately be encountered. Thus, for example, in an animal study where the route of exposure may be ingestion or injection, it may be necessary to apply appropriate toxicokinetic adjustments to address human inhalation exposure. Or, in a study in which the dose to the test animals was contained in food, it is necessary to consider how the bioavailability of the test substance in the food would affect the dose-response when considering human exposure from drinking water. Such toxicokinetic considerations are often based on models of varying complexity and realism (e.g., one compartment, multicompartment, physiologically-based pharmacokinetic). Traditionally, such considerations have been

addressed using point estimates for the various variables in toxicokinetic models. However, biological parameters (e.g., body weight, half-lives, blood volume) are truly distributed quantities reflecting population variability. Recently, probabilistic approaches have begun to be applied to such toxicokinetic models (see, for example [24] and [25]).

Risk Characterization

The risk characterization portion of the risk assessment process is intended to synthesize the outcomes from the earlier portions of the assessment into an overall quantitative estimate of the risk, to quantitatively address uncertainties in the estimate, and to provide a qualitative judgment of the overall confidence in the estimate. Having completed the dose–response and exposure assessment steps, the generation of the quantitative risk estimate is generally a straightforward process that involves applying the dose estimate from the exposure assessment to the dose–response relationship derived in the dose–response assessment. Quantitative treatment of uncertainties in the assessment (essentially the consideration and application of a series of adjustments) has traditionally been confined to the dose–response portion of noncancer risk assessments. The lack of such adjustments in cancer risk assessments reflects the general consensus that common cancer dose–response models already employ conservative assumptions and require no further adjustments to be sufficiently protective. In noncancer risk assessments, uncertainty adjustments have generally been applied according to the categories defined by the US EPA [26]. These are interindividual variability in sensitivity among healthy humans; interspecies differences in sensitivity (animal-to-human extrapolation); extrapolation from the results of subchronic exposure studies to lifetime exposure; extrapolation from a LOAEL dose to a (hypothetical) NOAEL; and a general modifying factor to address considerations of quality and reliability of the critical study (e.g., database insufficiency, small study size). Traditionally, uncertainty has been quantitatively adjusted separately for each category *via* the use of generic factors of 10, and, less commonly, 3. For example, a LOAEL derived from an animal study might be divided by three factors of 10 (i.e., a single factor of 1000) to account for (a) LOAEL-to-NOAEL, (b) animal-to-human, and (c) average human-to-sensitive human extrapolations. The original rationale for the use of

values of 10 (or 3) for these adjustments appears to have been rather arbitrary. Attempts to provide an empirical and probabilistic basis for such uncertainty adjustments are ongoing [12, 27–29], and appear to provide some (after-the-fact) justification for the traditional approach. Even with uncertainty adjustments generally limited to a maximum of 3000 or 10 000, in practice, the final estimate of a noncancer risk may be driven more by the uncertainty adjustments than by the dose–response data from the critical study.

The description of the overall confidence in the assessment is generally qualitative, and based on professional judgment about the completeness of the overall database (including the availability of data on reproductive, and developmental effects as well as chronic toxicity), the appropriateness of the critical effect, the adequacy of the design and execution of the key study, the data quality, and the appropriateness of the models employed. For noncancer assessments, confidence is generally ranked as high, medium, or low. For cancer assessments, the weight of evidence has historically been ranked according to one of several scales [5, 30, 31] that express the likelihood that the substance is a human carcinogen independent of the quantitative estimate of cancer risk. This determination involves several factors, including whether there is adequate evidence of human carcinogenicity from human studies, the extent to which the substance is carcinogenic in various species strains and/or sexes of test animals, the extent to which tumors observed in the animal models are physiologically and biochemically applicable to humans, and data from *in vivo* and *in vitro* studies, which give insight into the compound's mode of action.

Environmental Health Triage, Chemical Risk Assessment for

Preventing and protecting against environmental, occupational, and food-related chemical hazards is typically the primary goal of quantitative methods developed to assess environmental chemical risks (*see Environmental Health Risk; Environmental Hazard; Occupational Risks*) [1–5]. Protective regulatory and industrial hygiene measures are not designed to predict chemical risk or casualties. Extensive human pharmacokinetic, epidemiological, and/or clinical-trial data that allow reasonably unbiased estimates of risk for ionizing radiation and medical pharmaceuticals simply do not exist for most toxic industrial chemicals (TICs) or chemical threat agents (*see What are Hazardous Materials?; Environmental Risks*). Consequently, assessments of environmental chemical risks generally entail substantial uncertainty that is typically addressed by routine, health-protective application of “uncertainty” factors designed to guarantee acceptable levels of minimal risk [6]. However, less biased approaches may be preferable in some circumstances. Civil litigations (“toxic tort”) or criminal prosecutions require “more likely than not” or “beyond a reasonable doubt” standards of evidence, respectively, and in such cases unbiased assessments of environmental chemical harm may be required. Application of appropriate quantitative methods would be necessary to help meet such standards. Timely, unbiased assessment of chemical risk can also be important for effective insurance and disaster planning. In general, such unbiased assessment is needed whenever circumstances require choosing among trading off or prioritizing options associated with different chemical risks or different combinations of chemical and other risks [7].

Trade-off contexts concerning health are most dramatically illustrated in the case of urgent military coarse-of-action decisions, or emergency-response situations involving, e.g., airborne chemical threats (*see Counterterrorism*). Airborne chemical threat assessment systems now link real-time plume modeling and mapping capabilities with a variety of

toxic exposure guidelines, but none provide a systematically consistent way to compare risks that involve chemical exposures. If planners and responders cannot reliably compare chemical risks, or compare chemical *versus* nonchemical risks, then they cannot prevent or minimize associated casualties in a risk-based fashion. Reliable comparison of consequences associated with response alternatives will be critical whenever resource constraints or exposure-related complexities force a choice among possible options. Under such conditions, current approaches do not permit risk-based choices, and so will inevitably produce *ad hoc* decisions that tend to allow preventable casualties.

A risk-based approach to trade-offs is possible only if responders use unbiased information on chemical toxicity to predict residual casualties associated with alternative response strategies [7]. Current protective guidelines for acute and chronic chemical exposures [8–12] cannot serve this purpose because they incorporate a number of “uncertainty” factors and conservative assumptions that may vary quite substantially in combined magnitude from chemical to chemical, depending on scope and quality of available toxicity data. Planning and response strategies that effectively prevent exceedance of such conservative guidelines will clearly achieve risk-based consequence management. However, accidental or terrorism-related dispersion of toxic chemicals may involve either of two factors that complicate response and recovery decisions in ways that can make conservative chemical exposure guidelines irrelevant to effective consequence management. First, widespread dispersal of hazardous materials may create exposure scenarios that are potentially *complex*, by involving multiple exposed populations, agents (chemical, perhaps also biological and/or radiological), contaminated media, exposure routes, exposure durations, and/or types of casualty (acute, chronic, quasi-threshold, stochastic, short-term, and/or long-term). Secondly, logistic constraints, clustering of multiple events in time, and the sheer magnitude of damage incurred may limit response and recovery resources, either in the short-term or for extended or indefinite periods. Resource constraints and exposure-scenario complexities will, at times, make it impossible for planners and responders to operate within a traditional *environmental health protection* paradigm, which focuses on preventing the realization of conservatively estimated risks. Instead, decision makers will

be forced to operate within an *environmental health triage* paradigm [13], which focuses on making trade-off (triage) decisions that mitigate the greatest amount of expected casualty.

Protective chemical exposure guidelines appropriately incorporate substantial and widely varying degrees of conservatism, which depend on the nature of available dose–response data. Trade-off and priority-setting decisions require unbiased estimates of expected casualties. Such best estimates are not readily available, in easily accessible form, for most of the wide array of chemicals of concern. Consequently, no readily accessible, reliable basis for risk-based planning or consequence management is available for incidents that require comparing casualties from different chemical agents, or from mixtures of chemicals and other sources of risk (e.g., radiation, biological agents, or evacuation measures). What is missing is a comprehensive database of unbiased estimates of chemical toxicity and associated uncertainty characterizations. To address chemical emergency situations that require trade-off and prioritization decisions, a fundamentally new, general approach to assessing and managing chemical risks is needed [13, 14]. A scientifically peer-reviewed process, actively coordinated by agencies tasked with supporting emergency response, would also clearly contribute to progress toward new data structures and methods to support effective environmental health triage.

The following example of unbiased chemical risk assessment illustrates how and why a triage context should alter the protection-oriented, safety-factor approach traditionally applied to evaluate the acceptability of chemical exposure scenarios. The hypothetical triage situation considered posits that, due to practical short-term limits on available resources, emergency responders must choose between two immediate scenarios: (1) allow a group of trapped office workers to inhale 120 ppm Methyl Isocyanate (MIC) in air for 10 min, or (2) evacuate the workers by means that entail inhalation of 500 ppm Hydrogen Fluoride (HF) in air for 10 min. To protect against severe or lethal toxicity in a general population, acute exposure guideline levels (so-called AEGL-3 values) imply that no 10-min respiratory exposure should exceed an air concentration of 1.2 ppm MIC, or of 170 ppm HF [9]. Scenario 1 involves an exposure that is 10-fold, and scenario 2 an exposure that is threefold, greater than the corresponding AEGL-3

value. However, the AEGL-3 levels for MIC and HF have built-in safety factors of 6 and 1000 respectively, relative to corresponding (LC_{50}) concentrations likely to be lethal to 50% of exposed adults [13]. So scenario 2 implies exposure to about 50%, and scenario 1 to only 1%, of an LC_{50} . If forced to choose, responders should therefore choose scenario 1 rather than 2. More explicit, probabilistic methods are required to address more complicated triage scenarios that involve near- LC_{50} exposures, multiple chemicals, susceptible subpopulations, and/or time-varying concentrations [9, 13].

Environmental Risk Assessment of Water Pollution

KENNETH T. BOGEN

Environmental Monitoring

Conceptual Framework for Environmental Risk Assessment

Risk assessment has become an increasingly important tool for environmental decision making (*see Environmental Health Risk*). Risk assessments are being performed in application to the spectrum of environmental issues including such concerns as hazardous waste cleanups, permitting activities for water and air discharges, for land and water management decisions related to open land, forests, watersheds and estuaries, and for establishing environmental quality standards and guidelines (*see Air Pollution Risk; Hazardous Waste Site(s); Water Pollution Risk*). Inherently interdisciplinary, the field of risk assessment applied to the environment is evolving rapidly, despite associated uncertainties in assessment methodologies and data limitations. The result is that risk assessment and management procedures are now widely employed, including being dictated by the mandates of regulatory agencies throughout developed countries. However, it is also clear there are substantial needs for the development, use, and sharing of information including environmental data, assessment methods, and insights gained from interacting with decision makers and the public, to improve risk assessment protocols and risk management.

For the public to participate in making risk-based decisions, it is essential that the concepts of risk assessment be understood by the general public (*see Risk and the Media*). Hence, the scientific community must translate risk assessment approaches to simple terms, to ensure understanding is gained by the general public.

To put the concept of environmental risk assessment into more perspective, quantitative risk assessment (QRA) in the environmental arena may include three broad situations: (a) a source of contamination release/site exists, (b) a future activity is to be planned which will release some level of contaminants, or (c) an accident or terrorist activity may involve release of a toxic chemical (*see What are Hazardous Materials?*). To respond to any and/or all of these, routine and specific environmental

monitoring is essential. While specific environmental monitoring for a particular site may be designed to provide direct and accurate information for an existing source, for a future activity or accidental release, background data pertinent to the location are essential. Although models relating emission sources and their impacts to human receptors are employed in all situations, confidence in the model predictions is improved with data obtained by environmental monitoring.

The basic framework of any environmental health risk assessment is (a) exposure/dose assessment, (b) dose-response toxicity relationship (*see Dose-Response Analysis*), and (c) risk characterization. Apparent from the diversity of components, this basic framework is inherently interdisciplinary. The first part of the framework, exposure/dose assessment, is generally addressed by environmental engineers and scientists who specialize in environmental monitoring and modeling. The overall framework of the exposure/dose assessment is illustrated in Figure 1.

Source Characterization

Source characterization begins with hazard identification in terms of a chemical and/or an array of chemicals. This includes contaminated sites, industrial pollution sources (both point and nonpoint) for water, air, and solid wastes, and uses and transportation of toxic chemicals. Source monitoring represents an essential part of comprehensive source characterization with source characterization including information such as the location, quantity of contaminant release, frequency of discharge (e.g., continuous or intermittent), and so on.

Methods for Estimating Chemical Releases

The methods most commonly used in estimating emissions/discharge of pollutants include the following:

- *Continuous emission/discharge monitors (CEMs)*

CEMs continuously measure (with very short averaging time) and record actual emissions/discharge during operations. CEM data may also be used to estimate emissions for different operating and longer averaging times.

Figure 1 Conceptual framework for an exposure/dose assessment

- *Source testing*

Emission/discharge rates are derived from short-term measurements taken at an emission stack or waste discharge point. Emission data may then be extrapolated to estimate long-term emissions/discharge from the same or similar sources.

- *Material balance*

Emissions/discharges may be determined based on the amount of material that enters a process, the amount that leaves the process, and the amount shipped as part of the product itself.

- *Emission factors*

An emission factor is a ratio that relates the emission of a pollutant to an activity level at a plant that can be easily measured, e.g., an amount of material processed or an amount of fuel used. Given an emission factor and a known activity level, a simple multiplication yields an estimate of the emissions.

- *Fuel analysis*

Emissions may be determined based on the application of conservation laws. The presence of certain elements in fuels may be used to predict their presence in emission streams. For example, sulfur dioxide (SO₂) emissions from oil combustion may be calculated based on the concentration of sulfur in the oil. This approach assumes complete conversion of sulfur to SO₂. Therefore, for every kilogram of sulfur (molecular weight = 32 g) burned, 2 kg of SO₂ (molecular weight = 64 g) are emitted.

- *Emission estimation models*

Emission estimation models are empirically developed process equations used to estimate emissions from specific sources.

- *Surveys and questionnaires*

Surveys and questionnaires are commonly used to obtain facility-specific data on emissions and their sources.

- *Engineering judgment*

Engineering judgment is employed when the specific emission estimation techniques, such as stack testing, material balance, or emission factor are not possible; instead, the estimation is made by an engineer familiar with the specific process.

Examples of Emission Factor Information

- *AP-42*

One of the most frequently cited resources for emission factors to the air is the USEPA document, *Compilation of Air Pollutant Emission Factors (AP-42)*. This document contains pollutant emission factors for point and area sources. AP-42 is available at <http://www.epa.gov/ttn/chief/ap42/index.html>.

- *Emission factor databases*

Several emission factor databases are currently available in easy-to-access formats. These tools include Factor Information Retrieval (FIRE) Data System (<http://www.epa.gov/ttn/chief/fire.html>) and Air Clearinghouse for Inventories and Emission Factors – CD-ROM, <http://www.epa.gov/ttn/chief/airchief.html#order>.

- In addition, one should conduct a search of technical papers for source test and background information for the emission source category or pollutants in question. One can conduct this search using USEPA library services or through government document depositories at local universities. Examples of references and documents that one should review include miscellaneous private sector resources. For example, the National Council of the Paper Industry for Air and Stream Improvements, Inc. (NCASI) compiles, through a highly focused research program, reliable environmental data and information on the forest products industry.

Source characterization for existing sources is often accomplished by emission/discharge monitoring that includes source sampling and laboratory chemical analyses to ascertain quantity of emissions and discharges. For facilities still in the planning stage, best estimates of emission estimates must be obtained through other sources, which are expected to be similar in operation.

The Toxics Release Inventory (TRI) (<http://www.epa.gov/tri/>) database [1] contains information on specific toxic chemical releases for more than 650 toxic chemicals that are being used, manufactured, treated, transported, or released into the environment.

Broad classifications of sources are listed below.

- *Soils*
 - application of agricultural chemicals;
 - application of sewage sludge and treated/untreated wastewater for irrigation;
 - residues from transportation sources;
 - waste disposal.
- *Surface water*
 - runoff from agricultural and urban land;
 - treated, untreated, and accidental discharges from cities and factories;
 - atmospheric deposition of pollutants to lakes.
- *Groundwater*
 - leaking underground tanks and pipelines;
 - wastewater injection wells;
 - leachate from landfills.
- *Air*
 - stacks and vents;
 - leakages from storage tanks, flanges, valves;
 - handling of raw materials, products and their evaporation/volatilization.

Fate and Transport of Chemicals in the Environment

Once the source characteristics have been established, fate and transport of contaminants through monitoring and/or by mathematical modeling is essential to estimate the exposure and/or dose experienced by the receptor, as the next phase in the risk assessment (see **Fate and Transport Models**). This requires gathering data to quantify the constituents in each

of the compartments (air, water, soil, etc.) plus understanding the transformations which may occur from one compartment to another (e.g., volatilization of a chemical from water to air). Because constituents can change media, for many situations it is necessary to employ multimedia modeling to complete the hazard analysis. Before discussing these models which account for physical, chemical, and biological transformations, the properties of chemicals that influence the fate and transport must be addressed. The considerations must include the various attributes of the chemicals, e.g., volatility, viscosity, and density, since these features will influence the pathways by which the chemical may migrate; e.g., a highly volatile chemical may volatilize and hence travel as a gas and be inhaled by a receptor. Alternatively, a dense solvent such as tetrachloroethylene (PCE) may sink as a separate phase to the saturated groundwater and create an exposure pathway to a receptor *via* drinking water.

Important Fate and Transport Properties, Processes, and Parameters of Environmental Contaminants

Several factors contribute to the migration and transport of chemicals in environmental media. For example, in groundwater, does a chemical released into the groundwater cause an exposure hazard *via* consumption of groundwater as a water supply? Alternatively, the volatility of the chemical may be sufficiently high that the chemical volatilizes and creates an exposure scenario by the vapor entering into the basement of a house and hence an inhalation exposure to the resident.

Examination of a contaminant's physical and chemical properties may determine the extent of environmental partitioning, migration, and/or attenuation. A number of important physical and chemical properties, processes, and the parameters may affect the environmental fate and/or cross-media transfers of environmental contaminants including the physical state, water solubility, diffusion, dispersion and volatilization, biodegradation and photolysis (or photodegradation), hydrolysis, and oxidation/reduction (redox reactions). More details on these processes are provided, for example, in reference [2].

One of the important influences on risk exposure scenarios, and used herein to demonstrate the

Figure 2 Major components of the partitioning of contaminants between environmental compartments [Reproduced from [2]. © John Wiley & Sons, Ltd, 1993.]

complexity of risk assessment procedures, is the partitioning of a chemical between several phases within a variety of environmental matrices. The partition coefficient is a measure of the distribution of a given compound between two phases and is expressed as a concentration ratio. Several measures of the partitioning phenomena are enumerated below and their application in environmental phase transformation is shown in Figure 2.

- *Water/air partition coefficient*

The water/air partition coefficient (K_w) relates the distribution of a chemical between water and air. It consists of an expression that is equivalent to the reciprocal of Henry's law (H), i.e.,

$$K_w = \frac{C_{\text{water}}}{C_{\text{air}}} = \frac{1}{H} \quad (1)$$

Where C_{air} is the concentration of the chemical in air (expressed in units of $\mu\text{g l}^{-1}$). This coefficient is referred to as the *washout ratio* for the removal of gaseous air pollutants from air to the water phase during rain or snowfall.

- *Octanol/water partition coefficient*

The octanol/water partition (K_{ow}) is defined as the ratio of a chemical's concentration in the octanol phase (organic) to its concentration in the aqueous phase of a two-phase octanol/water system, represented by:

$$K_{ow} = \frac{\text{Concentration in octanol phase}}{\text{Concentration in aqueous phase}} \quad (2)$$

This dimensionless parameter provides a measure of the extent of chemical partitioning between water and octanol at equilibrium. It has become a particularly important parameter in the study of environmental fate of organic chemicals.

K_{ow} can be used to predict the magnitude of an organic constituent's tendency to partition between the aqueous and organic phases of a two-phase system, such as surface water and aquatic organisms. The higher the value of K_{ow} , the greater the tendency of an organic constituent to adsorb to soil or waste matrices containing appreciable organic carbon or to accumulate in biota.

- *Organic carbon adsorption coefficient*

The sorption characteristics of a chemical may be normalized to obtain a sorption constant based on organic carbon, which is essentially independent of any soil material. The organic carbon adsorption coefficient (K_{oc}) provides a measure of the extent of partitioning of a chemical constituent between soil or sediment organic carbon and water at equilibrium. Also called the *organic carbon partition coefficients*, K_{oc} , is a measure of the tendency for organics to be adsorbed by soil and sediment, and is expressed by

$$K_{oc} (\text{ml g}^{-1}) = \frac{\text{Microgram of chemical adsorbed per gram weight of soil or sediment organic carbon}}{\text{Microgram of chemical dissolved per milliliter of water}} \quad (3)$$

- *Bioconcentration factor (BCF)*

The BCF is the ratio of the concentration of a chemical constituent in an organism or whole body (e.g., a fish) or specific tissue (e.g., fat) to the concentration in its surrounding medium (e.g., water) at equilibrium, given by

$$BCF = \frac{(\text{Concentration in biota})}{(\text{Concentration in surrounding medium})} = \frac{\left[\left(\frac{\text{Microgram of chemical per gram biota such as fish}}{\text{Microgram of chemical per milliliter medium such as water}} \right) \right]}{\left[\left(\frac{\text{Microgram of chemical per gram biota such as fish}}{\text{Microgram of chemical per milliliter medium such as water}} \right) \right]} \quad (4)$$

The BCF indicates the degree to which a chemical residue may accumulate in aquatic organisms, coincident with ambient concentration of the chemical in water; it is a measure of the tendency of a chemical in water to accumulate in the tissue of an organism. In this regard, this is related to the concentration of the chemical where the fish are feeding, or biota BCF for that chemical. Thus, the average concentration in fish or biota is given by

$$C_{\text{fish-biota}} (\mu\text{g kg}^{-1}) = C_{\text{water}} (\mu\text{g l}^{-1}) \times BCF \quad (5)$$

The BCF is important in determining the risk, for example, *via* food-chain modeling where necessary assumptions involve tracing of successive levels of uptake through the food chain. For understanding this type of modeling, data for one of the environmental media are necessary and hence samples must be collected, as was done in reference [3] and then transformed to other parts of the food chain by procedures outlined in the following paragraphs.

Subsequently, food-chain modeling as input to the environmental risk assessment requires quantification of the BCF, which defines the equilibrium ratio of the concentration of the substance in the exposed organism (including vegetation and plants) to the concentration of the substance in the surrounding environment. In simple mathematical terms, soil-to-plant BCFs are defined as (after [4])

$$BCF_{\text{veg}} = \frac{C_{\text{veg}}}{C_{\text{soil}}} \quad (6)$$

where, BCF_{veg} is the BCF for vegetation, C_{veg} is the concentration of the chemical in vegetation ($\mu\text{g kg}^{-1}$ (dry weight)), and C_{soil} is the concentration of the chemical in soil ($\mu\text{g kg}^{-1}$ (dry weight)). The value of BCF for a toxicant depends on its chemical

properties, environmental conditions, and biological factors such as the organism's ability to metabolize the substance.

BCF magnitudes are related to *n*-octanol/water partition coefficient, K_{ow} (e.g., see [5]) and are constituent-specific. Uncertainties in estimation of BCF will be directly transformed into uncertain estimates of risk magnitudes. While wishing to remain conservative in the quantification of risk to err on the side of protection of humans and the environment, an underestimated BCF may eclipse safety and may result in a false sense of protection.

Standardized protocols for estimating BCFs exist for a number of aquatic species including, for example, the USEPA's recently updated fish and oyster BCF test guidelines [6, 7]. However, experimental determination of BCF is expensive and demanding and, as a consequence, measuring the BCFs of the many thousands of chemical substances that are of potential regulatory interest is simply not possible. This is obviously true for new chemicals such as those reviewed under the US Toxic Substances Control Act [8]. The dimensions of uncertainty also include the BCF from soil to vegetation to examine intake of toxic pollutants directly from the plants. Several options are commonly relied upon for estimation of the BCF. As per reference [9], one method for dioxins and furans is to rely upon bioaccumulation equivalency factors (BEFs) as a measure of congeners bioaccumulation potential relative to 2,3,7,8-(tetra chloro dibenzo dioxin (2,3,7,8-TCDD); see **Health Hazards Posed by Dioxin**). BEFs are estimated as a ratio between each dioxin and furan congener-specific biota-sediment accumulation factor to that of 2,3,7,8-TCDD [10, 11] as

$$BEF_i = \frac{BSAF_i}{BSAF_{\text{TCDD}}} \quad (7)$$

where BEF_i is the bioaccumulation equivalency factor for the i th congener, $BSAF_i$ is the biota-sediment accumulation factor for i th congener, and $BSAF_{\text{TCDD}}$ is the biota-sediment accumulation factor for 2,3,7,8-TCDD.

The estimates of BCF_i for each of the i congeners is then determined from

$$BCF_i = BCF_{\text{TCDD}} \cdot BEF_i \quad (8)$$

where BCF_i is the soil-to-plant bioconcentration factor for the i th congener (kg^{-1}), BCF_{TCDD} is

the soil-to-plant bioconcentration factor for 2,3,7,8-TCDD (1 kg^{-1}).

An alternative procedure, based on $\log K_{ow}$, provides estimates of BCF_i , from regression equations of the general form

$$\log BCF = a \log K_{ow} + b \quad (9)$$

where a and b are empirically determined constants, and K_{ow} is the n -octanol/water partition coefficient. Numerous versions of equation (9) have been published, but the broadly applicable (i.e., not class-specific) equations generally have slopes close to unity and negative intercepts [8]. The USEPA [9] currently uses the equation of reference [12] for estimating soil-to-plant BCF in which $a = -0.578$ and $b = 1.588$.

Such equations (e.g., see [13]) provide approximate magnitudes of the BCF for nonionic, nonmetabolized substances with $\log K_{ow}$ in the range of 1–6 for aquatic animals like fish and has been used extensively (as cited in Meylan *et al.* [8]). Alternatively, for the BCF in plants from soil, Travis and Arms [12] is extensively used. The main limitation of the Travis and Arms equation is that they have considered only 29 chemicals having $\log K_{ow}$ up to 6.89 (and polybrominated biphenyl, $\log K_{ow} = 9.35$). However, Travis and Arms have considered only one dioxin, TCDD (out of 29 chemicals) and, therefore, estimating BCF for other dioxins and furans using their equation may add to uncertainty in risk assessments. However, recently, Sharma *et al.* have demonstrated that observed BCFs for dioxins and furans from the field study are generally much higher (3–575 times – for 15 compounds and for octa chlorinated dibenzofurans (octa-CDF) 2770 times) than those computed by the USEPA method and are higher by a factor of 3–650 (for eight compounds) computed by the K_{ow} model [3]. These findings indicate that use of model-based BCFs may result in underestimation

of the risk or hazard and, pertinent to the completion of environmental risk assessments, demonstrates the need for careful development of data and, to the extent feasible, the necessity for collection of environmental data.

Contaminant Transport, Fate, and Modeling

The modeling of contaminants describes the pathways, phase transformation, and chemical transformation. Most of the models are based on simple concepts of mass conservation. Figure 3, in a simplistic way, presents the environmental models.

A specific example model for transport of soil to groundwater is depicted in Figure 4.

Another example of transport and transformation of air contaminant is illustrated in Figure 5.

As apparent from Figure 5, the exposure concentrations of a contaminant depend on several factors including:

- dispersion by atmospheric advection and diffusion;
- reduced by deposition, transfer to other media, and transformation reactions; and,
- meteorological parameters
 - wind parameters (direction, speed, and turbulence)
 - thermal properties (stability).

A typical multimedia equilibrium distribution of a fixed quantity of a chemical, in a closed environment at equilibrium, with no degrading reactions, no advective processes, and no intermedia transport processes (e.g., no wet deposition or sedimentation) is shown in Figure 6.

A multimedia environmental model like the one shown in Figure 6 uses physical–chemical properties of chemical. Three types of chemicals are treated

Figure 3 Conceptual environmental model: equations are solved to equate mass gained and mass lost

Figure 4 Transport from soil to groundwater

Source	Transport	Receptor
Emissions time and duration	Wind speed and direction turbulence	Humans plants buildings
Characteristics height volume flow temperature	Physical and chemical transformations	Monitoring

Figure 5 Transport and transformation of air contaminants (after Boubel *et al.* 1994)

Figure 6 Equilibrium multimedia model description. A: deposition/rain washout; B: resuspension/evaporation; C: evaporation/super saturation; D: ground water movement; E: sedimentation; F: resuspension

The success of a modeling assessment may depend on how well the model fits with the measurements. Thus, environmental monitoring that incorporates sampling, analysis, interpretation of data, and quality assurance and quality control is essential for the success of a modeling exercise. We may need, for example, to utilize monitoring data to provide quantification of coefficients in the mathematical models, to allow accurate characterization of risks. The availability of monitoring data for purposes of calibrating mathematical models greatly improves the veracity of the monitoring results and *vice versa*.

While the sampling of water, soil, and food products present challenges, environmental sampling may be much more challenging. For example, to ensure capture of measurable quantities of contaminants (e.g., for air monitoring, approximately 200–1000 m³ must pass through the sampling device and chemicals of interest) need to be retained on the sampling device. Further, there may be complexities due to, for example, diurnal and seasonal variation. For example, significant levels of the ozone may be just 3–4 h in a day while for the remainder of the day, the ozone may be at background concentrations. This also implies that the averaging time of the measurements becomes crucial. For example, a short-term peak concentration may be more harmful/toxic than long-term values (chronic) but the relevance depends on the source chemical, the migration pathways, and the scenarios of exposure of the receptor. For some compounds, especially those having long-term chronic carcinogenic effects, annual averages may be necessary (e.g., for benzene, a known carcinogen).

Receptor Characteristics

The attributes of the receptor influence the potential for the receptor to become ill. For example, what is the exposure timeframe of the receptor? The size of the receptor (child *versus* adult) is important since the potential to cause cancer is a function of the size of the individual (milligram per kilogram of weight).

Statistical Analyses of Monitoring Data in Support of Risk Assessment

As apparent from the preceding, environmental monitoring data are important inputs to environmental risk assessments (*see Environmental Health Risk*), to allow assignment of coefficients within the models. Unfortunately, environmental monitoring data tend to have characteristics that make the application of standard statistical methods difficult and/or inappropriate [14].

Examples of issues with interpreting the data include the data record length may be brief and may have skewness, thereby violating the assumptions implicit in standard statistical tests. The requirements of many of the more frequently used statistical tests must be validated to ensure the application of the tests is appropriate (e.g., see [15] for guidance).

Another problematic characteristic of environmental monitoring data is that the environmental data are often “censored” (*see Censoring*). That is, the data have a lower limit or, less frequently, an upper limit, beyond which a monitoring result is reported as “not detected” or “off-scale”. Statistically, this causes a change in the shape of the data distribution that may violate assumptions of specific statistical models and

require the use of alternate methods. Finally, natural systems tend to be highly complex and variable, and confounding effects, such as seasonality, temperature, or matrix stratification may need to be extracted, to remove noise from the data.

These features stress the difficulty with statistical interpretation of environmental data. There is a need for the analysis procedure to be sensitive to small changes (e.g., early detection of contamination is desirable) and yet a point of diminishing marginal returns for data collection may also occur. The result is that the analyst must be inventive in terms of how statistical analyses proceed. For the variety of reasons previously indicated, there is not a single approach to statistical analyses as input to environmental risk assessment. Instead, what is frequently needed is a series of approaches, each of which possesses useful attributes that may be appropriate in addressing a particular question.

Samples of environmental quality are just that, namely subsets of the populations that are of interest. To clarify, a limited number of monitoring samples will never fully describe every condition found in the population, i.e., every possible subset of the environment. The challenge then is to acquire a representative sample for use as part of the environmental risk assessment, to estimate population parameters with a given probability. The result is that in many cases, estimates of environmental quality must be developed from only very brief data records, brief being with respect to both temporal and spatial considerations. Even in cases with substantial quantities of data, there may only be a limited amount of information that is usable to address a specific question.

In addition to natural variability, the acquisition of monitoring data is also subject to collection and analysis errors. Errors in sampling procedures, inadequate sample storage and preservation techniques, and laboratory analytical errors are examples of errors in environmental data sets.

There is always a degree of uncertainty associated with each discrete measurement of environmental quality. In interpreting data, each discrete measurement represents a range of statistically probable values instead of a single value. Uncertainty can be estimated by considering replication and repeatability. Replication is a measure of the variation in results obtained by the same operator in a given laboratory using the same apparatus to make successive determinations on identical test material within a short period

of time. Often this is done during quality assurance and quality control testing of laboratories, to ensure the results are trustworthy. Replication represents the analytical uncertainty in acquiring monitoring data. Conversely, repeatability is a quantitative expression of the random error associated in the long run with a single operator in a given laboratory obtaining successive results with the same apparatus under constant operating conditions on identical material. Repeatability is a measure of the natural or sample variability. Note that a systematic error or bias in analytical results may be introduced in the field or laboratory due to sampling, handling, and/or analysis techniques, and such error may only be detected by making interlaboratory or intertechnician comparisons using the same samples.

The fact that sampling errors are inherent in random data does not mean, however, that statistical manipulations and sophistication can in any way overcome faulty environmental data. The quality of any statistical analysis as input to a risk assessment, is no better than the quality of the data utilized. Furthermore, statistical considerations cannot be used to replace judgment and careful thought in analyzing data. Statistics must be regarded as a tool or an aid to understanding, but never as a replacement of careful thought [15].

Statistical methods also suggest the ways to ascertain and handle the uncertainties in the monitoring data. In practice, with the help of a few measurements (e.g., number of samples <20) probability distribution functions can be generated for each parameter and from the derived distributions, random numbers can be generated as the surrogate of actual observations. This implies that infinite number of realizations can be generated and utilized in a model to develop probabilistic exposure scenarios, a procedure referred to as *Monte Carlo simulation*. For example, such an example for lead distribution in various food items is shown in Figure 7.

Conclusions

Use of environmental risk assessment and management is becoming increasingly important in decision making for environmental problems. There is substantial information available in the technical literature upon which to rely, and there is important merit in considering the collection of additional, site-specific data to ensure that the risk assessments are

Figure 7 Monte Carlo simulation to address uncertainties of measurements

pertinent, and appropriate, to a particular application. Frequently, there are so many environmental variables (chemical-specific, as well as media-specific) that the value of relying on site-specific data is very real, as long as it is feasible to do so. Clearly, there is an essential linkage between environmental risk assessment, and the data upon which the environmental risk assessment relies. While there is merit in obtaining additional data, there are points at which diminishing marginal returns occur for additional data collection efforts.

Environmental Performance Index

Contrary to other policy fields such as the economy, health care, and education, the environment remains mired in deeply emotional debates and rhetoric that makes limited use of data and performance assessments (*see* **History and Examples of Environmental Justice**). While partially the result of a persistent lack of relevant information, environmental policy requires the same data-driven, rigorous assessments used to make decisions on economic and other issues. Moreover, effective environmental management is not possible without monitoring ecological conditions and measuring the effects of policy responses to environmental pressures (*see* **Ecological Risk Assessment**).

Recognizing this need and the prevailing gap of quantitative measures of environmental performance, a team of researchers and policy experts at the Yale Center for Environmental Law and Policy (Yale University) and Columbia University's Center for International Earth Science Information Network (CIESIN) with support from the World Economic Forum developed the Pilot 2006 Environmental Performance Index (EPI) [1].

The EPI measures the performance of country-level environmental activities on key policy concerns. It is designed to support and complement the environmental indicators of the United Nations Millennium Development Goals (MDG), which are the international community's most concerted effort, to date, to eradicate poverty and promote human development using goal-specific indicators with explicit time frames.

The EPI Framework

The EPI is a target-bound, composite index measuring environmental policy outcomes on two broad, inextricably linked objectives: (a) protecting human environmental health and (b) maintaining ecological vitality. National performance on each objective is measured on six widely adopted policy categories through a total of 16 indicators shown in Figure 1.

Although input and process indicators are required for choosing policy solutions within the context of

benefit–cost analysis (*see* **Risk–Benefit Analysis for Environmental Applications**), the ultimate goal is to achieve stated objectives for on-the-ground conditions. Therefore, the EPI indicators are outcome oriented to the extent data availability and understanding of causal relationships permit.

As shown in Table 1 the performance targets of the 16 indicators reflect relevant long-term public health or ecosystem sustainability objectives drawn from international agreements, international or national standards, and prevailing consensus among scientists.

Although orthogonal indicators are often desirable in index development, environmental pressures frequently have multiple impacts such that the separation of issues into mutually exclusive policy categories is not feasible in all cases. For this reason the indicators *particulate concentration*, *water consumption*, and *timber harvest rate* are each associated with two policy categories (*cf.* Figure 1).

Data Transformation

Aggregation of the 16 EPI indicators into performance indices for the six policy categories, and ultimately the EPI, requires transformation to the same scale. This is achieved by converting each indicator to a standardized proximity-to-target measure such that a value of 100 corresponds to meeting (or exceeding) the target and a value of zero to being farthest away from the target among the 133 countries included in the EPI. Prior to this conversion, extremely low values, which may represent data anomalies (*see* **Low-Dose Extrapolation**) rather than true measurements, are winsorized at both the fifth percentile and target values. This means that the lowest performing 5% of the observations of each indicator are set to the fifth percentile value and observations exceeding the corresponding target are reduced to the target value. The calculation of proximity-to-target values $\tilde{y}_{ij}$ is shown in equation (1), where y_{ij}^w denotes the winsorized value for the i th country ($i = 1, 2, \dots, 133$) and j th indicator ($j = 1, 2, \dots, 16$), and t_j is the target of the j th indicator.

$$\tilde{y}_{ij} = \begin{cases} 100(t_j - y_{ij}^w)/(t_j - \min(y_{ij}^w)), & t_j \geq \max(y_{ij}^w) \\ 100(y_{ij}^w - t_j)/(\max(y_{ij}^w) - t_j), & t_j \leq \min(y_{ij}^w) \end{cases} \quad (1)$$

Figure 1 The EPI is constructed in a two-step procedure by averaging 16 proximity-to-target indicators using weights derived from principal component analysis and expert judgment. Numbers indicate the weight of the component within the EPI

Weighting

The six policy subindices are calculated as the weighted average of their underlying proximity-to-target indicators. Since weights can be interpreted as the importance given to the respective indicator, which is likely to vary among countries, no uniformly “correct” weights exist. Thus, a combination of principal component analysis (PCA) and expert judgment is used to specify the indicator weights. The PCA identifies three distinct policy dimensions – environmental health, biodiversity and habitat protection, and sustainable energy – and the estimated indicator loads are used to calculate the weights (*cf.* Table 1). In the absence of sufficient justification for differential weights for the remaining three categories, equal weighting is applied. The EPI then gives 50% weight to the environmental health policy category and 10% weight each to the remaining five policy categories, thereby reflecting the political dominance of public environmental health concerns (*cf.* Table 1).

Results

Of the 133 countries included in the EPI none has achieved all 16 performance targets and likewise no country scored zero on all measures, although four countries scored less than 100 on every single indicator: Jordan, South Africa, Thailand, and Tunisia. The range of observed scores for the EPI and policy categories is substantial, as Table 2 illustrates for a sample of 25 countries.

Policy makers, interested in identifying what makes some countries successful environmental stewards while others struggle to meet their responsibilities, benefit from EPI “peer group” analyses on the basis of common geographical, political, environmental, and other factors (see Table 2). For example, per capita gross domestic product (GDP) measured in purchasing power parities (PPP), to account for differences in cost of living, is a useful discriminator to identify countries that are likely to perform differently on the indicators *child mortality* and *nitrogen loading*.

Table 1 Indicators and performance targets in the Pilot 2006 Environmental Performance Index^{(a)(b)}

Policy category	Indicator	Performance target
Environmental health	Concentration of particulates (urban)	10 $\mu\text{g m}^{-3(c)}$
	Indoor air pollution	0% households using solid fuels ^(d)
	Access to improved drinking water	100% access
	Access to sanitation	100% access
	Child mortality (1–4 years)	0 deaths per 1000 pop 1–4 years
Air quality	Concentration of particulates (urban)	10 $\mu\text{g m}^{-3(c)}$
	Regional ozone concentration	15 ppb ^(e)
Water resources	Nitrogen loading	1 mg l^{-1}
	Water consumption	0% oversubscription
	Wilderness protection	90% of wild areas protected
Biodiversity and habitat protection	Eco-region protection	10% for all biomes
	Timber harvest rate	3% ^(f)
Productive natural resources	Water consumption	0% oversubscription
	Timber harvest rate	3% ^(f)
	Overfishing	No overfishing (score of 0)
	Agricultural subsidies	0%
Sustainable energy	Energy efficiency	1650 TJ/million US\$ GDP
	Renewable energy	100%
	CO ₂ emissions	0 net emissions ^(g)

^(g) Strict interpretation of the goal of the 1992 UN Framework Convention on Climate Change

Regardless of the choice of peer group, environmental policy is a heterogeneous mixture of successes and shortfalls for most countries. For example, although the average country is 82% along to meeting its water resources targets, it has covered only 51 and 54% of the distance to the Biodiversity and Habitat Protection and Air Quality goals, respectively. Similarly, timber harvest rate, which is measured

only for countries with existing natural or plantation forests, is near the sustainability target in most countries but almost every country fails to reach the wilderness and eco-region protection targets.

In addition to the EPI's environmental outcome measures, analyzing its relationship to other environmental, economic, and development indices also offers insights for policy. Without implying causal

Table 2 Sample of 25 countries ranked by EPI score. Shown are also the scores for the six policy objectives: environmental health, air quality, water resources, biodiversity and habitat protection, productive natural resources, and sustainable energy^{(a)(b)}

^(b) To place the EPI and policy category scores into appropriate context selected peer group memberships are provided in the fourth column. They are in order of appearance OECD: Organization for Economic Cooperation and Development; EU: European Union; FTAA: Free Trade Agreement of the Americas; POP: high population density; ASEAN: Association of Southeast Asian Nations plus China, Japan, and South Korea; AU: African Union; NIS: Russia and Newly Independent States; D: desert countries; LDC: least developed countries

links, strong performance on the EPI correlates statistically significantly with per capita GDP ($R^2 = 0.70$), the 2003 Human Development Index (HDI) (the 2003 HDI refers to approximately the same period as the EPI) ($R^2 = 0.77$) [2], and the environmental governance indicator of the 2005 Environmental Sustainability Index ($R^2 = 0.56$) [3]. Explanations for these linkages proposed in the literature [3–6] include that integrated thinking about environmental, economic, educational, and health-related issues combined with a political governance system that permits and encourages the finding of solutions leads – on average – to greater environmental net benefits than sectoral policies alone.

Outlook

The Pilot 2006 EPI work is in progress and is only the beginning of a deeper quantitative analysis of environmental performance and its drivers. At this stage of development, the emphasis is on identifying the appropriate components of a performance matrix, the building of the best possible indicators, and solving methodological questions in the aggregation procedure. The EPI is thus meant to stimulate discourse on these issues as well as to promote the use of quantitative assessments in environmental policy.

Comparative Risk Assessment

Environmental Hazard

History and Examples of Environmental Justice

TANJA SREBOTNJAK

Environmental Remediation

Environmental remediation concerns the quality of the environment, and how to support decision making to decide on how to handle it. Research into exposure pathways has illustrated the dangers of pollutants, such as fine dust, *heavy metals* (see **Lead**; **Arsenic**), or volatiles exuded from former petrochemical sites. Additionally, there has been increasing insight provided into pollutant decay and reabsorption, as well as into complex phase transfer processes, e.g., between soil and groundwater, or air and surface water, allowing a more detailed and forward looking assessment of pollution evolution. Such understanding is necessary given (a) the growing demand for suitable land for habitation and agricultural/industrial use, (b) frequent changes in landuse types that tolerate different levels of contamination, and (c) growing awareness of the effects of pollution among the public. Strict laws detailing precise pollution and exposure limits exist, at least in industrialized nations. The cost of remediation is also rising, and identification of the most cost-effective approach requires detailed knowledge that allows correspondingly detailed treatment depending on specific local contamination.

Environmental remediation concerns assessment of the quality of the three main environmental compartments to define ways to reduce pollution levels to tolerable limits for a given landuse. This is done by assessing the hazard, the exposure, and the dose–response, together commonly called *risk characterization*.

We consider each of the three major environmental compartments: air, water, and soil (see **Air Pollution Risk**; **Environmental Risk Assessment of Water Pollution**; **Soil Contamination Risk**). All can be contaminated and all require a very careful treatment. Soil is the most stable compartment, in the sense that contamination may remain more or less stable for years. Water and air are more fluid and immediate changes in quality may occur. Our main concern will be the soil, as here the major statistical contributions can be made. Remediation ranges from leaving as is, to a total excavation and cleaning of contaminated soil in order to reach a contamination level appropriate for a given landuse. For residential use, a near zero pollution level may be required, whereas

only a reduced level may suffice for the soil below a parking lot. In the soil we generally work with two thresholds: a target value and an intervention value. The target value defines a clean quality of the environment, whereas the intervention value is a more operational value setting the threshold of intervention by either the government or local engineering companies.

We proceed as follows. First we consider the concept of risk in environmental remediation. Next, we consider spatial statistical methods (see **Spatial Risk Assessment**) to indicate their advantages in the remediation domain. We then proceed with *in situ* and *ex situ* remediation and decision support and make the step toward a model. We finish the entry with some concluding remarks.

What Is Risk?

While being easy to define at a general level, a detailed risk characterization makes data collection for a 100% accurate assessment for larger areas impossible or impractical. Various approaches have been developed to assess environmental pollution.

Risk is defined as the probability of a given adverse outcome, commonly calculated as the product of *hazard*, *social* and *physical vulnerability*, and *elements at risk*. A more complete assessment can also include *value*, i.e., the potential cost of a hazardous event. In the context of environmental remediation a similar definition is used [1]:

$$\text{Risk characterization} = \text{hazard} \times \text{exposure} \times \text{dose-response} \quad (1)$$

The overall risk is then a function of the hazard, in terms of its nature, concentration and distribution, the exposure of a given person or group of persons, in terms of intensity, frequency and duration, and the specific relationship between dose and adverse health effects [1, 2]. A similar definition also applies for adverse consequences on the environment or animals.

Hazard identification concerns identification of a substance or agent posing a risk, and assessing its potential to cause adverse effects to health or environment. In soils this translates into high spatial variability that depends on factors, such as soil types, impermeable layers, pollutant type and mobility, and groundwater seepage. In water and air, while

more homogenous, distribution and concentration are subject to currents and wind direction, respectively. In all cases this translates into strong spatial and potentially temporal variability.

Exposure assessment aims at characterizing and quantifying the intensity, duration, and frequency of exposure to the given hazard, ideally for every person. This considers the various pathways of such contact, e.g., *via* direct ingestion of polluted soil, dust, water or air, consumption of soil or dust attached to vegetables, or consumption of pollutants *via* vegetables or meat. For an accurate assessment, mobility of people and local landuse may also be included.

Dose-response considers the specific relationship between the dose of hazardous agent and potentially adverse health or environmental consequences. It is a function of factors such as age, gender, health status, as well as frequency and intensity of contaminant ingestion (see **Dose-Response Analysis**).

In environmental remediation, we are mainly considering spatial risks, i.e., risks to be related to spatial variables. We consider risk as the relation between a spatial variable and a threshold. This is denoted as a spatial variable $X(s)$ in relation to a threshold x_c . We shall not consider the obvious extension toward time variables or toward space-time variables in this article. We can then formulate the hazard as a probabilistic concept:

$$\text{Hazard} = \Pr(X(s) > x_c) \quad (2)$$

It specifies therefore the probability that at a location s , a threshold value x_c is exceeded. In order to make valid statements, stationarity assumptions have to be made, leading to applicability of geostatistical methods. Because of the exploratory nature of this article, we shall not go very deep into these matters [3].

The existence of threshold values depends on the effect of exceeding or not exceeding these values in relation to the quality of life. In all environmental compartments there are critical values, which in case of exceeding require additional measures by local authorities. In air quality measurements, typical thresholds of current scientific concern exist for ozone, NO_x and SO_x . These values typically have a direct effect on the well-being of the population. In groundwater the effects are usually indirect, as much of the drinking water and the irrigation water is cleaned before further application. In groundwater,

however, various chemical toxicants like heavy metals and polyaromatic hydrocarbons are of concern. Usually, the response time is relatively long between threshold exceeding and measurable effects on the (human) population. Even more, in soil studies the time between a measurement above a threshold level and measurable effects to the (human) population is usually rather long. Typical contaminants are heavy metals, mineral oils and polyaromatic hydrocarbons (see **What are Hazardous Materials?**).

The traditional approach to such a problem is a remedial action aimed at multifunctionality [4]. Thus, all the functions the soil can possess, given its natural characteristics, are to be reestablished. This single-perspective view is just one possibility to face the problem. Multiperspective views include elements other than soil protection and have caused a shift of attention from *ex situ* remediation to *in situ* remediation. Within the multifunctional framework, where concentrations are the norm, *in situ* techniques are aimed at reaching threshold values in the shortest possible time. In contrast, techniques in the triple-perspective REC-framework, where *risks*, *environmental merits*, and *costs* are taken into account simultaneously, aim at optimizing within the three-dimensional framework.

Risk Assessment Approaches

Deterministic Methods

A deterministic approach quantifies all parameters required in the risk equation. Soil pollutant concentrations are measured, as well as the amount a person is exposed to, and how that person will react to the pollutant. This leads to a simple source-pathway-receptor framework. First used in the early 1980s it is still being used, for example in the United Kingdom's site-specific assessment criteria (SSAC) procedure [2]. The SSAC approach is very detailed, taking account of exposure duration and time-averaged body weight or vegetable consumption rates of the receptor. The mathematical implementation of the approach, however, is straightforward. Point values used in the parameterization, e.g., pollutant concentrations collected from spot measurements, however, cannot reflect the high spatial-temporal variability of pollutant concentrations [1, 5]. They are, therefore, unsuitable for an assessment of how many people will be affected or exposed. Hence, such approaches

calculate the maximum exposure, thus aiding the *precautionary principle* [6, 7]. Increasing safety factors have traditionally been added, to be on the safe side, leading to risk overestimation. Irrespective of isolated peak concentrations or exposures the entire area is assigned the maximum risk value, leading to excessive and unnecessary remediation costs.

Probabilistic Methods

In the early 1990s, methods were developed that incorporated a characterization of variability, i.e., the natural variation, as well as uncertainty, or lack of knowledge [1]. This allows one to consider the variability in pollutant concentration within the soil, as well as that between individuals, but also to assess the uncertainty in exposure estimation. An important method is Monte Carlo simulation (MCS), which takes account of the variability of the natural phenomenon [8]. Instead of producing a single risk map, MCS produces a distribution of plausible maps that all reasonably match the sample statistics. It shows both the uncertainty of the model parameters and how this uncertainty influences the final risk estimate. In addition to MCS, regression analysis, and analysis of variance (ANOVA) have been used. However, the temporal dimension, critical given the dynamics of natural systems, is frequently neglected.

MCS is further useful to assess the combined effect of several input parameters [1]. Given the multitude of parameter combinations and resultant assumptions and generalizations, a further problem is that it is often not possible to provide risk values with a certainty desired by decision makers. A related problem is the frequent use of precise parameter values and probability distributions [7]. One way to overcome this is by using intervals or probability bound analysis, although these do not reflect well the distribution shape or central tendency. Statistical analysis, however, should be more than a simple tool, and hence should include expert knowledge, especially for site-specific parameter estimation.

Beyond simple MCS the utility of geospatial statistics combined with probabilistic human health risk assessment can be assessed [8]. This allows for a more realistic assessment of spatial variability and local uncertainty, e.g., in soil contamination levels. Such a combined approach better incorporates the spatial dimension in contaminant concentration and distribution, thus allowing a more realistic analysis.

Hybrid of Probabilistic and Fuzzy Methods

To address the uncertainty in the evaluation criteria, Chen *et al.* [9] state that complex parameters such as landuse patterns or receptor sensitivities cannot be modeled with probability functions. Thus, approaches based on fuzzy set theory have been developed that are better equipped to represent the parameter uncertainties. The authors describe a hybrid approach that uses probabilistic methods to address the variability in pollution source and transfer modeling, and fuzzy tools for the evaluation criteria. They also provide a detailed methodology and illustrate with an example. A similar hybrid approach was used by Li *et al.* [10] to evaluate risk from hydrocarbon contamination, who also used the fuzzy set methodology to model different remediation scenarios (from partial to nearly complete cleanup), as well as the spatio-temporal risk variation over different time periods.

In situ and ex situ Remediation

In environmental remediation a distinction is made between *ex situ* and *in situ* remediation. *In situ* remediation concerns techniques like bioremediation, soil washing or extraction, and soil venting [11], whereas containment techniques prevent contamination to migrate. Soil washing uses the solubility of a contaminant, which will dissolve in the percolate and by means of a special withdrawal system the percolate is pumped up and treated. Soil venting aims at volatilization and biodegradation of the contaminant in the unsaturated zone, followed by a vapor treatment system to remove the contaminants from the vapor. Air sparging involves injection of air into the saturated zone for the dual purpose of volatilizing organic components and enhancing biodegradation [11]. *Ex situ* soil remediation concerns excavation of contaminated soil, cleaning this soil at an independent location and putting it back after cleaning, possibly at the same location.

Spatial Statistical Methods

In many remediation studies, the need to quantify risks can be solved by means of geostatistical and other spatial statistical methods. Indicator kriging and probability kriging have been usefully used for risk mapping. Optimal sampling procedures have been

developed to sample an area such that maximum information is obtained given the limited amount of budget for taking observations. Optimization has also taken place for air quality networks and in groundwater (and surface water) observation networks. Spatial simulation methods have been used to show realizations of the random field underlying observations. Different types of observations (measured and organoleptic) have been combined in a geographical information system. Space–time statistics have in particular been useful to assess the changes in concentrations and quality of the environment (see **Spatiotemporal Risk Analysis**). Modern approaches by means of model-based Geostatistics are a recent step forward. Finally, the combination of spatial statistical methods with soil, air, and groundwater models has been performed in many systems and detailed case studies.

Example: a Cost Model for Environmental Remediation

Sanitation of contaminated soil is an expensive task, which is difficult to assess. Estimated costs are sometimes exceeded by 100% [12]. Here we show the use of a cost model to a former gasworks site in the harbor area of the city of Rotterdam [13]. In 1994, an integrated soil inventory was carried out (10 observations/ha). We concentrate on the upper layer (0–0.5 m), containing the largest set of the full vector of observations (Figure 1). The five contaminants indicative of the spatial extent of contamination are cyanide, mineral oil, lead, polyaromatic hydrocarbons PAH-total, and zinc.

Four environmental thresholds classify areas according to the degree of contamination: *S* value: (*Safe* or *Target level*): maximum concentration of a contaminant to maintain multifunctionality, *T* value: intermediate level between low and serious soil pollution, *I* value (*Intervention level*): if this value is exceeded the functional properties of the soil for humans, fauna, and flora are seriously degraded or are threatened to be seriously degraded and the BAGA level (“*Chemical waste*”): at this level the soil is chemical waste and should be carefully treated (Table 1).

A cost model combines the thresholds with remediation techniques. Ten classes with different processing costs are distinguished. The highest degree of

Figure 1 Location of sample points in the area

Table 1 Environmental thresholds for five contaminants. All thresholds are expressed in (mg kg^{-1})

Contaminant	<i>S</i> value	<i>T</i> value	<i>I</i> value	BAGA
Cn	5	27.5	50	50
Mineral oil	50	2525	5000	50 000
Pb	85	307.5	530	5000
PAH	1	20.5	40	50
Zn	140	430	720	20 000

pollution of any contaminant determines whether a soil cube should be excavated or not, depending upon different remediation scenarios. Dividing the area into 5760 squares of 7 by 7 m^2 , we find that treatment of the area costs €3.11 M. More details can be found in Stein and Van Oort [14].

Concluding Remarks

Environmental remediation has received quite some recent attention, with the advance a growing awareness of the effects of contamination for health and the environment, and with the advance of spatial statistical methods to quantify the associated risks. A current trend is a further focus on individual risks,

a better quantification of those, and a more realistic assessment. Advances can be expected at each of the components of risk assessment: realistic modeling, improved observation methods e.g., by using remote sensing derived methods, and realistic vulnerability assessments.

ALFRED STEIN AND NORMAN KERLE

Environmental Risk Assessment of Water Pollution

Environmental risk due to water pollution is an ongoing every day problem. Municipal wastewater systems are one of the largest pollution sources to surface waters, however; other major sources include residential and industrial discharges, and agricultural runoff, dumped into rivers directly or by seepage from contaminated groundwater. Threats from chemicals may come from sources such as pesticide use and waste disposal. Air pollution and land pollution also affect water quality (*see Air Pollution Risk; Soil Contamination Risk*).

Water resources are considered as one of the main factors affecting our life, industries, agriculture, and economics. Therefore, we must properly assess the risk of water pollution from these resources. Consequently, measures should be taken in order to protect water sources from pollution. For these reasons, we have to identify its contents and detect the sources that cause these contents to deviate from their safety and healthy levels.

This work presents an illustration of two statistical techniques that can assess the risk of surface water pollution from bacterial and chemical sources, as applied to a sample from Tigris river water after it has passed through the Baghdad metropolitan area. The first is an adaptation of existing methods to lognormal data, while the second is an application of intervention analysis with time series data.

Data Description

The data consisted of samples collected over 48 weeks. At each sample point six measurements were made, three on bacterial variables (coliform, fecal coliform, and plate count), and three on chemical variables (chloride, T-hardness, and conductivity). Samples were taken from two selected locations on Tigris river during 1988. The first was located north of Baghdad, approximately 35 km from city center (upper stream), and the second was situated south of Baghdad, approximately 20 km from city center (downstream). These two locations bracket most of

the pollution sources. Furthermore, to account for the river width and water current speed, measurements were replicated at four points across the river at time t . These measurements were also correlated. The study area brackets major pollution sources such as chemical factories and vegetation farms that use fertilizers. Almost all of these sources are on the west side of the river. These six measurements generated six time series, each of 48 observations (with four readings across the river) in which successive observations were serially dependent and may be nonstationary, or with seasonal effects.

Adapting the Lognormal Model

Suppose D_{kt} is the k th downstream measurement ($k = 1, 2, 3, \dots, K$) across the river observed at time ($t = 1, 2, 3, \dots, T$) on a pollutant content in the water (chemical or bacterial), and U_{kt} denotes the corresponding upper stream measurement. Define the ratio between observations at downstream and upper stream, by $R_{kt} = D_{kt}/U_{kt}$; hence $D_{kt} = R_{kt}U_{kt}$. Considering all major pollution sources on one side of the river (west side) and taking into account the width of the Tigris river along with the water current speed, a recursive interdependency between the four readings across the river can be derived. The ratio R_t can be rewritten as (see [1])

$$\begin{aligned} R_t &= R_{0t} \prod_{k=1}^K L_k = R_{0t} \left[\prod_{k=1}^K L_k^{1/K} \right]^K \\ &= R_{0t} [G_K]^K \quad t = 1, 2, \dots, T \end{aligned} \quad (1)$$

where R_{0t} is the initial value for the ratios, $(L_1, L_2, \dots, L_K)$ is a positive random vector and G_K is the geometric mean (GM) for $L_1, L_2, \dots, L_K$. Therefore, from relations (1) we can deduce that the ratio R_t is proportional to the geometric mean of the ratios at sample points across the river. A significant deviation of the expected value of R_t from unity (>1) indicates an increase in pollution level. Letting $L_k = 1 + \delta_k$, and substituting the Taylor expansion of $\ln(1 + \delta_k)$ in equation (1), $\ln R_t$ can be approximated by

$$\ln R_t = \ln R_{0t} + \sum_{k=1}^K \delta_k \quad (2)$$

By the additive central limit theorem $\ln R_t$ is asymptotically normally distributed, and by definition R_t will have a lognormal distribution, $R_t \sim \Lambda(\gamma, \mu, \sigma)$, where γ is location (threshold) parameter, μ is the mean, and σ is the standard deviation. Using R as a generic symbol for R_t the random variable $Y = \ln(R - \gamma)$ is normal, $N(\mu, \sigma^2)$, $\sigma > 0$, and $R > \gamma$.

The parameters γ, μ, σ of the lognormal distribution will be estimated using “modified moment estimation” (MME) (see [2]). For an ordered sample of size n , the estimating equations are given by

$$\gamma + e^\mu e^{\sigma^2/2} = \bar{r} \quad (3)$$

$$e^{2\mu} e^{\sigma^2} (e^{\sigma^2} - 1) = s^2 \quad (4)$$

$$\gamma + e^\mu \exp(\sigma E Z_{1,n}) = r_1 \quad (5)$$

where $\bar{r}$ and s^2 are the sample mean and variance (unbiased); r_1 is the observed first-order statistics, of a random sample of size n , and $E Z_{1,n}$ is the expected value of the first-order statistic for a sample of size n from $N(0, 1)$.

From equation (4) the unbiased estimator for μ is

$$\hat{\mu} = \ln\{s[e^{\hat{\sigma}^2}(e^{\hat{\sigma}^2} - 1)]\}^{-1/2} \quad (6)$$

and $\hat{\sigma}$ can be found using Table 5 or Figure 2 in [2], by entering the table or the figure with $J(n, \hat{\sigma}) = s^2/(\bar{r} - r_1)$ to read $\hat{\sigma}$. Finally, γ can be estimated from equation (5).

The summary of the coliform data collected from the Tigris river is as follows: $K = 4, n = 48$ pairs of measurements resulted in 48 ratios(r), $\bar{r} = 53.295, s = 113.99, r_1 = 1.51$. Using the MME procedure, $\hat{\sigma} = 1.32, \hat{\gamma} = 0.782, \hat{\mu} = 3.976$. The ratios of coliform bacteria “geometric means” follow a lognormal distribution, $R \sim \Lambda(0.782, 3.976, 1.32)$. Hence $\ln(R - \gamma)$ is normal. Testing $H_0 : E(R - \gamma) = 1$ against $H_1 : E(R - \gamma) > 1$, yield Z score = 9.54, which is highly significant ($p \approx 0$) (see [1]).

Using Intervention Analysis in Time Series

Consider the data $(\Lambda, z_{t-1}, z_t, z_{t+1}, \Lambda)$, which represents a time series over equal time intervals under certain intervention effects. The time series model for Z_t , before intervention (upper stream), can be written as follows:

$$\phi(B)Z_t = \theta(B)a_t \quad (7)$$

where $\phi(B)$ and $\theta(B)$ are polynomials in B , the backshift operator, $(BN_t = N_{t-1})$, and $\{a_t\}$ is sequence of white noises [3]. The generic model after intervention (downstream) can be written as:

$$y_t = f(\alpha, \xi_t, t) + N_t \quad (8)$$

where y_t is some transformation of Z_t ; ξ_t is exogenous variable (intervention), α is the set of unknown parameters, and N_t represents is a noise. The noise N_t can be transformed to a white noise using equation (7). The exogenous variable model ξ_t can be represented by the dynamic model:

$$f(\delta, \Omega, \xi_t, t) = \sum_{j=1}^I \eta_{tj} = \sum_{j=1}^I \left[\frac{\Omega_j(B)}{\delta_j(B)} \right] \xi_{tj} \quad (9)$$

where η_{tj} is the dynamic transformation of ξ_{tj} and $\delta_j(B), \Omega_j(B)$ are polynomials in B of degrees r_j and s_j , respectively, and I represents number of intervention (which is equal to 1 for our analysis). Transforming η_t to ξ_t can be achieved by the linear difference equation:

$$\delta(B)\eta_t = \Omega(B)\xi_t \quad (10)$$

A step function, $S(t, T) = \begin{cases} 0, & t < T \\ 1, & t \geq T \end{cases}$, can adequately represent the intervention variable ξ_t .

An output step change of unknown magnitude would be produced according to

$$\eta_t = \omega BS(t, T) \quad (11)$$

Finally the general intervention model can be written as follows:

$$Z_t = R(B)\xi_t + \phi^{*-1}(B)\theta^*(B)a_t \quad (12)$$

where $(\phi^*(B), \theta^*(B))$ are the estimates of $(\phi(B), \theta(B))$, and $R(B) = \Omega(B)/\delta(B)$. Equation (12) can be expressed in a regression format

$$Y_t = \beta X_t + a_t \quad (13)$$

where $Y_t = \phi^*(B)\theta^{*-1}(B)Z_t, X_t = \phi^*(B)\theta^{*-1}(B)\xi_t$ and $\beta = R(B)$. The least-squares estimate of β is $\beta^* = \sum_{t=1}^n y_t x_t / \sum_{t=1}^n x_t^2$ with variance $V(\beta^*) = \sigma_a^2 (\sum_{t=1}^n x_t^2)^{-1}$. Applying the methodology to the coliform data after transforming it to a stationary series, the Autoregressive Integrated Moving Average (ARIMA (0,1,1)) model showed a best fit to upper

stream series, with estimated noise model $N_t = (1 - 0.71529B)a_t$. For the downstream series, the least-squares estimate for the regression equation (13) is $Y_t = 79247X_t + 23218$, with $R^2 = 63.7\%$, for details (see [1]). The model and parameter tests were highly significant ($p \cong 0$) assessing a high risk of coliform bacteria concentration in Tigris river at the selected region. For test results on the other pollutants in Tigris river (see [1]).

Environmental Risk Regulation

Modern governments adopt laws and regulations to protect environmental quality and human health. The fundamental justification for environmental regulation is to control harmful externalities that arise when an individual, firm, or any other organization releases pollutants to the environment that cause harm to other people (e.g., air pollution from burning fossil fuels causes human death and disease, adverse effects to ecosystems, and alters global climate). Regulation may also be justified as a method to protect individuals and households from their own poor decisions, as when individuals may have insufficient information to make informed decisions (e.g., advisories to limit consumption of fish from contaminated water bodies).

Regulation of *environmental hazard* (see **Environmental Hazard**) involves questions of risk assessment, standard setting, and regulatory mechanism. Risk assessment describes how the probability and severity of harm depends on the level of pollution (see **Environmental Health Risk**). Standard setting is the choice of how much pollution to allow, and the regulatory mechanism is the legal framework, which influences how much each polluter can release.

Risk Assessment

Risk assessment characterizes the possible harms (or benefits) of exposure to a pollutant and their probabilities. Regulatory decision makers are interested in both the average risks in a population and the distribution or variability of risk in the population, including risks to the most highly exposed and most sensitive individuals. Population risks are often described in terms of the expected number of cases (e.g., fatalities or cancers), but this shorthand form of expression may be misleading. For most environmental risks, the identities of the individuals who suffer the adverse outcomes are unknowable both *ex ante* and *ex post*.

Risk assessment is conventionally divided into four components: hazard identification, dose–response assessment, exposure assessment, and risk characterization [1].

Hazard identification involves determining what health effects can be produced by the chemicals, radiation, or other agents, and under what conditions. For example, an agent may cause cancer or other disease, may be acutely lethal, or may cause some form of nonfatal illness, or reproductive anomaly. Hazard identification often relies on short-term tests of laboratory animals or microorganisms and yields a qualitative statement about the possible health consequences of exposure to an agent and the conditions under which these effects may occur (see **Environmental Hazard**; **Environmental Risks**).

Dose–response assessment involves determining how the type, severity, and probability of the health effects depend on exposure to the agent (see **Dose–Response Analysis**). Dose–response assessment is critical to characterizing risk for, as the sixteenth century physician Paracelsus recognized, “All substances are poisons; there is none which is not a poison. The right dose differentiates a poison and a remedy” [2].

For carcinogens, it is conventionally assumed that the type and severity of the cancer that may be caused is independent of dose but the probability of developing cancer is proportional to dose (for small dose levels), which implies a positive probability at all exposure levels above zero. This “linear no-threshold” model was initially motivated by the notion that a single genetic mutation can initiate a process that leads to development of cancer (see **Statistics for Environmental Teratogenesis**). In some cases, there may be a threshold dose below which the probability of harm is zero and above which the probability or severity of harm increases with increasing dose. The threshold model represents a situation in which the body’s immunological or other defense mechanisms can effectively protect against low doses, but are overwhelmed by higher doses of the agent. A third possibility is a “hormetic” dose–response function, in which a low dose of the agent may cause a beneficial effect but larger doses may cause a harmful effect (for example, exposure to sunlight promotes vitamin D production at low dose but causes skin cancer at high dose).

In some cases, risk assessment purports to identify a “safe” dose or exposure. For example, the “reference dose” is “an estimate (with uncertainty spanning perhaps an order of magnitude) of daily exposure to the human population (including sensitive subgroups)

that is likely to be without an appreciable risk of deleterious effects during a lifetime” [3]. In cases where the dose–response relationship has a threshold, the threshold dose satisfies this criterion but in cases with no threshold, identification of a “safe” dose depends on the definition of “safe”.

Exposure assessment involves determining the quantities of the agent to which individuals are exposed, together with exposure conditions such as route and time pattern when these influence the probability of harm. For some agents (e.g., carcinogens), the probability of the adverse effect is treated as a function of cumulative exposure over an individual’s lifetime. For others (e.g., acute toxins), the maximum exposure over a short period may be more relevant.

In some cases, dose is not explicitly considered and risk assessment substitutes an exposure–response or concentration–response function for a dose–response function. For example, assessments of the risk from exposure to air pollutants may describe the probability of adverse health effects as a function of the average daily or peak hourly concentration of the pollutant in ambient air (*see Air Pollution Risk*).

Risk characterization involves aggregating the results of the other three components to describe the risk, i.e., the potential health effects and their probabilities of occurrence, including uncertainty about these matters.

Standard Setting

Setting an appropriate standard for environmental risks requires balancing the benefits of reduced risk against the costs, or other harm incurred in reducing the risk (*see Risk–Benefit Analysis for Environmental Applications*). Any significant reductions (ancillary benefits) and increases (countervailing risks) in other risks should also be considered [4]. This comparison may be explicit, as when standards are based on economic evaluation, or implicit as when standards are based on criteria such as “protection of public health” or “as low as reasonably achievable”.

Benefit–cost analysis (BCA) is a method to account for all the significant consequences of a regulation, quantifying them in monetary units. BCA allows one to rank alternative policies by the expected

value of the net benefits (i.e., the expected difference between benefits and costs) to determine which of these produces the greatest expected gain to society. An alternative approach, cost-effectiveness analysis (CEA), measures some of the consequences in nonmonetary “effectiveness” units (e.g., “lives saved” or deaths prevented from a specific risk) and estimates the ratio of cost per unit effectiveness. CEA allows one to compare the efficiency with which policies produce units of effectiveness but the question of whether the beneficial effects justify the costs incurred requires an independent judgment.

Principles of Economic Evaluation

An environmental regulation will typically benefit some people and harm others. A critical question is how to determine whether the harm caused to some is outweighed by the benefit conferred on others. Economic welfare analysis begins with the assumption that one cannot reliably compare gains or losses in welfare to different people, i.e., if two people develop the same illness, one cannot determine who suffers more. Economic evaluation distinguishes two aspects of a change in social outcomes, efficiency and the distribution of well-being among people. A situation is defined to be *Pareto* or *allocatively efficient*, if it is not possible to change matters in a way that benefits at least one person without harming anyone. Many situations may be efficient but differ in the distribution of well-being in a population. If everyone at the dinner table prefers a larger to a smaller slice of pie, any division that leaves no crumbs is efficient.

Any change in environmental regulation that is a Pareto improvement is efficiency enhancing and there is a presumption that it should be adopted [5]. However, since many potential changes are neither Pareto superior nor Pareto inferior to the *status quo*, regulations are usually evaluated by whether they satisfy the Kaldor–Hicks compensation test: those who benefit from the change could provide monetary compensation to those who are harmed so that everyone prefers the change with compensation to the *status quo*. Whether a change that causes harm to some people yet satisfies the compensation test qualifies as a social improvement can be questioned. The arguments in favor of adopting the test include the following: (a) adopting policies that satisfy the

test expands the “social pie”, which at least admits the possibility that everyone gets a bigger slice; (b) if some redistribution of resources is desired (e.g., to reduce inequality), it may be better achieved through more direct transfers, such as taxation and welfare policies, than by adopting inefficient environmental regulations; (c) if society follows the compensation test routinely, the groups that benefit and are harmed will tend to differ from case to case and everyone may be better off than if decisions are made on some other basis.

BCA provides a method of determining whether a proposed change satisfies the Kaldor–Hicks compensation test. For an individual, benefits are measured as the maximum amount the person would be willing to pay to obtain the changes he views as beneficial and costs as the minimum amount of compensation he would require to accept the changes he views as adverse. Summing benefits and costs across the population determines whether those who gain would be able to compensate those who are harmed and still prefer the change.

Defining and Measuring Benefits and Costs

Economic evaluation attempts to measure the “social” or “resource” benefits and costs of a policy or activity. Some private benefits and costs increase or decrease social welfare, but others are simply transfers within a society. For example, a requirement to install catalytic converters in automobiles is a private cost to new-vehicle purchasers. It is also a social cost, because workers’ time and materials used to produce the catalytic converters cannot be used to produce something else of value. In contrast, a tax on gasoline purchases is not a social cost but a transfer from gasoline consumers to the government, which can use these resources to purchase other goods. (Imposing a gasoline tax may create a social cost by preventing consumers who would be willing to pay the cost of the gasoline, but not the cost plus the tax, from using gasoline.)

The social cost of an action to reduce environmental risk is the value of the resources used to reduce the risk. It may include the cost of control technologies (such as catalytic converters), changes in processes (such as substituting fuel injection for carburetion), or changes in inputs (such as substituting natural gas for petroleum fuel). When multiple technologies are

employed, one may be able to estimate the incremental cost by comparing the prices of the technologies, controlling for other factors using statistical methods. Alternatively, costs may be estimated using engineering models to project the quantities of resources required to produce the new technology and the market prices or other estimates of the social value of the resources. The costs of new technologies that have not yet been produced at commercial scale are necessarily rather speculative.

Benefits are estimated by “revealed-preference” or “stated-preference” methods [6, 7]. Revealed-preference methods are based on the assumption that an individual chooses from a set of available alternatives the one he prefers most. For example, the benefit of reduced mortality risk is often estimated by examining the extra compensation workers receive for more dangerous jobs [8]. Stated-preference methods rely on asking survey respondents what choices they would make in a clearly defined setting. For example, respondents may be asked if they would vote to support or oppose a law reducing air pollution from electric plants that would increase the price of electricity. Revealed-preference methods are often preferred since they are based on consequential choices. Stated-preference methods are more flexible since they are not limited to situations where the actual choices of people can be observed and respondents can be questioned about the attribute of interest, e.g., future changes in environmental risk.

Regulatory Mechanism

Regulations are classified as using “command-and-control” or “economic-incentive” mechanisms. Command-and-control mechanisms specify either the technologies that must be used to limit environmental pollution (e.g., “end-of-pipe controls” such as catalytic converters on automobiles), or the allowable quantity or rate of emissions (e.g., performance standards such as vehicle miles per gallon). Command-and-control instruments cannot be easily tailored to accommodate differences in pollution-control costs between firms and so they may not minimize the social cost of reducing pollution. Technology standards also require the government to select the technology, even though firms may have better information about the costs of alternative methods for reducing pollution.

Economic-incentive mechanisms provide firms with an incentive to account for the external costs of emissions, but allow them flexibility in how emissions are reduced. The primary forms of incentive-based instruments are taxes and tradable permits.

An emissions tax internalizes the external damages associated with a firm's pollution. It provides an incentive for firms to reduce emissions when the tax exceeds the incremental cost of emission reduction, and to not reduce emissions when the tax is less than this cost. If the tax is set equal to the social benefit of reducing a unit of pollution, the socially optimal level of pollution should be achieved.

Under a tradable-emission-permit system, a limited quantity of permits is issued and each firm is required to have a permit for every unit of pollution it releases. This establishes a performance standard but adds the option of interfirm flexibility. Firms may buy and sell permits among themselves. The permit price functions analogously to an emissions tax. Firms that can reduce emissions at a cost lower than the permit price will do so, and either buy fewer permits or sell any excess permits they may have. Firms that cannot reduce emissions at a cost lower than the permit price will rather purchase additional permits to cover their emissions.

Several case studies of environmental risk regulation including the application of risk assessment, BCA, and choice of regulatory mechanism are described in [9].

Environmental Risks

What Is Meant by the “Environment”?

The term *environment* in the context of environmental health has been defined based on a variety of different dimensions. In its 2006 comparative risk assessment of the environmental contribution to the global burden of disease, the World Health Organization (WHO) acknowledged that the term environment can include not only the physical environment, but can also be interpreted to include the natural, social, and behavioral components. This broad construction of environment is consistent with the definition offered by Last [1], “All that which is external to the human host. Can be divided into the physical, biological, social, cultural, etc., any or all of which can influence the health status of populations...” However, the WHO ultimately offered a more “practical” definition of the environment in the context of risk factors that can be modified to address environmental health risks as follows, “The environment is all the physical, chemical and biological factors external to a person, and all the related behaviors” [2].

The term *environment* can also be defined based on spatial and/or temporal factors. For example, spatial definitions of environment can be characterized (from narrowest to broadest) as personal, micro, local, metropolitan, regional, national, and global. With respect to exposure to airborne contaminants, the environment is often divided between the outdoors and indoors. The environment of an individual or a population can also be defined by the time frame and activities (i.e., time–activity patterns) of that individual or population.

The “environments” affecting health also have an inherently hierarchical structure that extends from the individual to the global levels. Individuals can determine some aspects of their personal environment, but environments at higher levels of organization, e.g., local, regional, and national, are not under their control, even if critical to health status.

One useful conceptual formulation of the structure of environments is the “microenvironmental model”, often applied to air pollution exposure and risk. In this model (1), total personal exposure (E) is the time-averaged pollutant concentration for an individual in

the various places, or microenvironments, where the person spends time. Thus,

$$E = \sum_i c_i t_i \quad (1)$$

where c_i is the pollutant concentration in microenvironment i , and t_i is the time spent there. In some microenvironments, the pollutant concentration might be affected by occupant activities, such as smoking – a source of airborne particles–while in others, concentration could be determined by population-level factors, e.g., traffic.

Environmental Health Risks

Risks to human health from environmental agents can occur from a wide variety of sources that can result in an increased risk of disease or injury *via* various biological or physiological processes, or of premature death. Rodricks [3] has proposed five broad categories of environmental agents that can increase the risk of adverse health outcomes: pathogenic agents; natural and synthetic chemicals; radiation; nutritional substances; and physical objects. Table 1 provides examples of specific types of agents under these broad categories.

For the purposes of this section of the encyclopedia, the focus is on natural and synthetic chemicals that are considered environmental pollutants, i.e., toxic substances introduced into the environment, or naturally occurring substances which have demonstrated an adverse impact on health, and also on radiation.

Environmental pollutants are typically categorized according to media-specific regulatory structures (e.g., air, water, and foods). These pollutants are regulated through limits on acceptable levels in these media, or through limits on the emissions from sources of these pollutants *via* these media into the environment. For example, the United States Environmental Protection Agency (USEPA) and the WHO have established ambient air quality standards and guidelines, respectively, that indicate the concentration of pollutants in the air to levels deemed to represent minimal (though not zero) levels of health risk. Similar types of acceptable pollutant levels have been established for surface and drinking water, as well as pesticide residue in foods.

Table 1 Five categories of environmental agents that can contribute to increased human health risks^{(a)(b)}

Pathogenic agents	Natural and synthetic chemicals	Radiation	Nutritional substances	Physical objects
Many microorganisms (bacteria, fungi, viruses, parasites)	Natural products (chemicals in foods, beverages, plants, animals, insects)	All forms of ionizing and nonionizing radiation (including heat, sound)	Constituents of foods and beverages that are necessary for nutrition	Weapons
	Industrial products and by-products			
	Consumer products			
	Pesticides, agricultural chemicals			
	Medicines, medical and diagnostic devices			
	Chemicals used for clothing, shelter, other physical structures and objects			Machinery/equipment/ tools
	Tobacco and its combustion products			Moving vehicles
	Substances used for fuels and their combustion products			Components of physical structures
	Substances of abuse			Water
	By-products and wastes from the above			Natural formation and products

^(a) Reproduced from [3]. © Heldref Publications, 1994.

^(b) Some subgroups contain many individual agents; naturally occurring chemicals in the diet probably make up the single largest subgroup of individual chemicals. Distinctions are made between pathogenic microorganisms that cause harm by invading the body and growing there, and those that produce chemical toxins outside the body that cause harm when ingested; the latter are in the group of natural chemical products. Similarly, though the constituents of physical objects are all chemicals, the agents of harm are the objects themselves, and the harm they may create (usually some form of physical trauma) is not related to the hazards of their chemical components

Figure 1 Example of multiple exposure pathways to environmental pollutants [Reproduced from [3]. National Institute of Environmental Health Sciences, 1994.]

Environmental pollutants can also be categorized according to the ubiquity of exposure and type of health outcome associated with exposure. For example, under the structure established by the US Clean Air Act, pollutants associated with cancer, neurotoxic or reproductive health effects, but with more limited population exposure, are classified and regulated as “hazardous air pollutants”, while exposure to “criteria air pollutants” is presumed to be more widespread, but typically not associated with more severe health outcomes, such as cancer. As discussed in the case study that follows, airborne particulate matter is an example of an exception to this classification approach, as it is classified as a criteria pollutant given its widespread exposure profile, even though it is associated with lung cancer and premature death.

In developed countries, increasing attention has been focused on environmental health risks associated with relatively low levels of exposure to well-studied pollutants such as airborne particulate matter and environmental tobacco smoke, as well as pollutants of emerging concern that have potential neurological effects, or those that affect the endocrine system and are associated with potentially adverse reproductive effects. Developing countries typically face environmental health risks associated with significantly higher levels of environmental

contaminants resulting from pollutant emissions from rapid industrialization, as well as home heating and cooking, and rudimentary sanitary practices.

Pathways and Routes of Exposure to Environmental Contaminants

Humans are exposed to environmental contaminants from diverse sources through various *pathways*. Pathways are the physical course taken by a contaminant from the source to the exterior of the exposed person or organism. These pathways include air, water, food, and soil contact. The contaminants are then transferred from the exterior to the interior of the exposed person or organism through several possible *routes* of exposure: inhalation (*via* air); ingestion (*via* water or food consumption); or dermal absorption (*via* water or soil contact). Figure 1 provides an illustration of the sequence from sources of pollution to human exposures pathways and potential routes of exposure, finally resulting in adverse health effects.

Exposure to some pollutants occurs *via* only one pathway. Carbon monoxide, a gas formed *via* incomplete combustion, pollutes outdoor and indoor air and is inhaled; breathing is the only pathway. By contrast, exposure to lead might occur through

inhaled air, water contaminated from lead-containing pipes, or ingestion of lead-contaminated dust.

Environmental and Occupational Health Risks

Environmental health risks can be distinguished from the risks to workers from pollutants in occupational settings in three significant categories: (a) the magnitude and susceptibility to disease of the potentially exposed populations, (b) the number of contaminants that populations are exposed to, and (c) the levels of exposure to the pollutants and the magnitude of excess risk resulting from such exposure.

The size of the populations potentially exposed to widespread environmental contaminants is typically two to three orders of magnitude larger than that of workers exposed to occupational pollutants. Whereas the size of worker populations potentially exposed to dangerous levels of specific contaminants is often in range of tens or hundreds of thousands, a population exposed to unhealthy levels of contaminants in the environment are typically in the range of tens or hundreds of millions. For example, the USEPA estimates that 133 million people in the United States (out of a total population of 281 million) lived in areas where monitored air quality in 2001 violated at least one health-based national air quality standard [4]. By comparison, the US National Institute of Occupational Safety and Health (NIOSH) estimates based on a survey taken in the early 1980s (the most recent data available) that approximately 2.5 million US workers were potentially exposed to the chemical 1,1,1-trichloroethane (TCE), one of the most ubiquitous chemicals used in industrial applications, though approximately 70% of workers exposed to TCE in occupational settings received no protection from these exposures [5, 6].

In addition to major differences in the size of exposed populations, there are significant differences in the susceptibility to disease or other adverse health outcomes from occupationally exposed populations as compared to the population exposed to environmental contaminants. Among those exposed to environmental contaminants are particularly susceptible subpopulations such as infants and children, the elderly, and those with preexisting disease, all of whom are usually not exposed to occupational pollutants. Workers in occupational settings

are generally considered healthier than the general population, and results of epidemiologic studies on the effects of workplace contaminants must account for this “healthy worker” effect before findings can be extended to the general population.

There are important differences in the scope of environmental *versus* occupational contaminants that pose a potential health risk to exposed populations. The general population is exposed to virtually thousands of pollutants and chemicals that potentially may pose a health risk, while the number of chemicals of concern in occupational settings is much more limited in scope. However, the levels of pollutant exposures and resulting health risks are typically orders of magnitude higher for occupational settings than in the general environment. Thus the health risk to any individual is typically much higher for exposure to occupational contaminants, while the population risk is generally higher from environmental pollutants owing to the large numbers of potentially exposed individuals.

Risk can be characterized at the individual and population levels. For individuals, either absolute or relative risk indicators may be applied. For populations, burden estimates are made that give the proportion of disease attributable to the environmental agent [7]. The most widely applied measure is the population attributable risk (PAR), which is described in equation (2):

$$PAR = \frac{P_E(RR - 1)}{1 + P_E(RR - 1)} \quad (2)$$

where P_E is the population prevalence of exposure and RR is the relative risk associated with exposure. The formula is useful for examining the interplay between patterns of exposure, risk to the exposed, and population risk. An exposure with very high relative risk as might occur for an occupational exposure has little impact on PAR if P_E is low. On the other hand, an exposure that is common, i.e., P_E is high, may contribute substantially to PAR, even if RR is low.

Environmental Health risks Case Study – The 1952 London Smog Episode

Perhaps one of the most dramatic examples of the public health consequences of environmental pollution occurred in London, England during December

Figure 2 Schematic of inversion and normal atmospheric conditions

5–9, 1952. The combination of a thermal inversion (Figure 2) and the increased burning of coal for heating resulted in a dramatic increase in the levels of particulate matter, sulfur dioxide, and other combustion-related air pollutants during this 5-day period. The air pollution smoke and fog (thus the term *smog*) experienced in this episode reduced visibility to near zero in some areas, and increased air pollution levels by up to a factor of 10.

The health consequences of this air pollution episode mirrored the rise in air pollution. Widespread cattle deaths were the first indication that these high levels of pollution would have major human health consequences. The daily death rate in London tripled over the course of this event, rising from about 300 to a high of 900 deaths per day [8]. The populations at greatest risk from exposure to these high air pollution levels were the elderly and those with preexisting respiratory disease. For example, mortality for persons with bronchitis and pneumonia

increased sevenfold as a result of this episode. In total, an estimated 4000 deaths were attributed to the immediate effects of the episode, and up to another 8000 deaths in the first quarter of 1953 have been linked to the air pollution exposures during this episode [9].

While current levels of air pollution in developed countries are now many times lower than those in the 1930s–1960s, and air pollution episodes such as the 1952 London fog are no longer experienced in the United States, Europe, and other developed countries, relatively high air pollution levels are still experienced by populations living in developing countries experiencing rapid industrial growth. Additionally, recent evidence from scientific studies indicate that even relatively low levels of air pollution that are more typical of air quality experienced in the United States, Europe, and other developed countries pose a substantial health risk. In the United States, an estimated 60 000 premature deaths each year from cardiopulmonary disease and lung cancer have been associated with exposure to outdoor particulate matter pollution [10].

Environmental Security

Environmental Security Defined

Environmental security has emerged as an increasingly important concern of governments and their defense establishments due to several trends that have the potential to threaten stability [1, 2]. These potential threat issues include: population growth; water scarcities and allocation; groundwater depletion; globalization; significant degradation of arable land; loss of tropical forests; greenhouse gas emissions and climate change; exacerbation of biological species loss; rapid urbanization; increasingly serious urban air and water quality problems; and increasing frequency of hurricanes, earthquakes, floods, and other natural disasters [3, 4].

Several definitions of environmental security exist and demonstrate that after more than two decades of discussion the concept of environmental security still has no widely agreed upon formulation [5, 6]. Examples include the following:

“Environmental security (ecological security or a myriad of other terms) reflects the ability of a nation or a society to withstand environmental asset scarcity, environmental risks or adverse changes, or environment-related tensions or conflicts.” [7];

“Science-based case studies, which meld physical science with the discipline of political economy, are a suitable vehicle for forecasting future conflicts derived in some measure from environmental degradation” [8];

“[T]hose actions and policies that provide safety from environmental dangers caused by natural or human processes due to ignorance, accident, mismanagement or intentional design, and originating within or across national borders.” [9];

“Environmental Security is a state of the target group, either individual, collective or national, being systematically protected from environmental risks caused by inappropriate ecological process due to ignorance, accident, mismanagement or design.” [10];

“Environmental security is protectedness of natural environment and vital interests of citizens, society, the state from internal and external impacts, adverse processes and trends in development that threaten human health, biodiversity and sustainable functioning of ecosystems, and survival of humankind.” [10];

“Environmental security is the state of protection of vital interests of the individual, society, natural environment from threats resulting from anthropogenic and natural impacts on the environment.” [10]

The discipline of “environmental security” is neither a pure security issue nor an environmental issue [7]. However, environmental issues are often security concerns because, even without directly causing open conflict, they can result in environmental perturbations or triggers that can destabilize the status quo and result in a loss of regional, national, and local political, social, economic, and personal security [4].

Environmental security concerns can be grouped into three general categories [10]: (a) security of the environment, which is a good in itself, (b) security from environmental change that can create societal instability and conflict, and (c) security from environmental change (e.g., water scarcity, air pollution, etc.) that would threaten the material well-being of individuals [10]. Common elements of environmental security definitions include public safety from environmental dangers caused by natural or human processes due to ignorance, accident, mismanagement, or design; amelioration of natural resource scarcity; maintenance of a healthy environment; amelioration of environmental degradation; and, prevention of social disorder and conflict (promotion of social stability) [11].

Environmental Security and Risk Management

Application of risk assessment in the field of environmental security is a challenging task. There are many compelling reasons to use the current risk assessment/management paradigm for environmental security applications [6]. These include a variety of acceptable/unacceptable risk criteria at different regulatory levels or under specific statutes representing local control of risk decisions, existing law, experience with the system, and proven flexibility in the risk-management decision-making phase. The implicit acceptable risk-management process is an administratively and legally established process with known methods to determine whether acceptable risks have been exceeded. In such cases, it is important that the acceptable risk level is looked at as a point of departure for consideration, and not as a bright line.

Even though the risk assessment paradigm successfully used by many agencies may be generally applicable to environmental security, its application requires incorporating an uncertainty in basic knowledge that is much larger than the uncertainty for current applications. Tools that are currently used for uncertainty analysis (such as probabilistic modeling, predictive structure–activity analysis, etc.) may not be easily applied to environmental security. An additional challenge is the balancing of multiple relevant decision factors, including the environmental and societal benefits, as well as risks associated with the specific policy option.

Additional consideration could be incorporated into the commonly used risk assessment paradigm through the use of comparative risk assessment [12]. Comparative risk analysis (CRA, *see Comparative Risk Assessment*) has been most commonly applied within the realm of policy analysis. Programmatic CRA has helped to characterize regional and national environmental priorities by comparing the multidimensional risks associated with policy alternatives [13]. At smaller scales, CRAs often have specific objectives within the broader goal of evaluating and comparing possible alternatives and their risks [14]. CRA studies have compared interrelated risks involving specific policy choices, such as chemical versus microbial disease risks in drinking water. Central to CRA is the construction of a two-dimensional decision matrix that contains project alternatives' scores on various criteria. However, CRA lacks a structured method for combining performance on criteria to identify an optimal project alternative [15].

Nevertheless, adding limited number of additional factors and its qualitative evaluation may not be enough for environmental security applications. Risk management requires balancing scientific findings with multifaceted input from many stakeholders with different values and objectives. In such instances, systematic decision analysis tools [16] are an appropriate method to solve complex technical and behavioral issues [15]. Given the uncertainty in all aspects related to environmental security, the structured, transparent, and justifiable tools offered by multicriteria decision analysis (MCDA) for quantifying both scientific and decision makers' values and views, as well as for developing a system of performance metrics consistent with regulatory requirements, may be especially valuable for this emerging field. Even though MCDA tools may not be able to resolve

contradictions in current risk estimates, application of MCDA tools can help bring further enlightenment by making trade-offs explicit. The development and implementation of such a framework will make clear what information should be collected to support decisions. MCDA tools, coupled with the value of information analysis and adaptive management, could provide a good foundation for both bringing together multiple information sources to assess environmental security risks and also for developing justifiable and transparent regulatory decisions [17, 18].

Framework for Incorporating Risk Assessment and Decision Analysis into Environmental Security Management

A systematic decision framework (Figure 1, from [15]) could be used as a generalized road map to environmental security decision-making process, including emerging threats [19]. Having the right combination of people is the first essential element in the decision process. The activity and involvement levels of three basic groups of people (environmental managers and decision makers, scientists and engineers, and stakeholders) are symbolized in Figure 1 by dark lines for direct involvement and dotted lines for less direct involvement. While the actual membership and function of these three groups may overlap or vary, the roles of each are essential in maximizing the utility of human input into the decision process. Each group has its own way of viewing the world, its own method of envisioning solutions, and its own societal responsibility. Policy and decision makers spend most of their effort defining the problem's context and the overall constraints of the decision. In addition, they may have responsibility for the final policy selection and implementation. Stakeholders may provide input in defining the problem, but they contribute the most input toward helping formulate a performance criteria and making value judgments for weighting the various success criteria. Depending on the problem and regulatory context, stakeholders may have some responsibility in ranking and selecting the final option. Scientists and engineers have the most focused role in that they provide the measurements or estimations of the desired criteria that determine the success of various alternatives. While they may take a secondary role as stakeholders or decision makers, their primary role is to provide the technical input necessary for the decision process.

Figure 1 Adaptive decision framework. Solid lines represent direct involvement for people or utilization of tools; dashed lines represent less direct involvement or utilization [Reproduced from [15]. © Pergamon Press, 2006.]

The process depicted in Figure 1 follows two basic themes: (a) generating management alternatives, success criteria, and value judgments, and (b) ranking the alternatives by applying value weights. The first part of the process generates and defines choices, performance levels, and preferences. The latter section methodically prunes nonfeasible alternatives by first applying screening mechanisms (for example, overall cost, technical feasibility, or general societal acceptance) and then ranking in detail the remaining options by decision analytical techniques (Analytical Hierarchy Process (AHP), Multi-attribute Utility Theory (MAUT), or outranking) that use the various criteria levels generated by environmental tools, monitoring, or stakeholder surveys. While it is reasonable to expect that the process may vary in specific details among regulatory programs and project types, emphasis should be given to designing an adaptive management structure. In contrast to traditional “command and control” approaches [17], adaptive management uses adaptive learning as a means for incorporating changes in decision priorities, and new knowledge from monitoring programs into strategy selection.

The tools used within group decision making and scientific research are essential elements of the

overall decision process. As with group involvement, the applicability of the tools is symbolized in Figure 1 by solid lines (direct or high utility) and dotted lines (indirect or low utility). Decision analysis tools help to generate and map stakeholder preferences as well as individual value judgments into organized structures that can be linked with other technical tools from risk analysis, modeling, monitoring, and cost estimations. Decision analysis software can also provide useful graphical techniques and visualization methods to express the gathered information in understandable formats. Linkov *et al.* [18] and Yatsalo *et al.* [20] present an example of MCDA assessments for two sediment management case studies utilizing four different MCDA software packages. Figure 2 presents just one example output. Criterium Decision Plus software [21] was used to implement a Simple Multi-attribute Rating Technique (SMART)/MAUT approach to quantitatively incorporate stakeholder value judgments on criteria along with technical measures for specific criteria weighting. Figure 2 shows an example of ranking of four sediment management alternatives. The wetland restoration alternative is the most preferable because of its environmental and ecological benefits. An upland disposal is ranked

Figure 2 Example of MCDA software output. Ranking of sediment management alternatives and sensitivity analysis using Criterion Decision Plus software [Reproduced from [22]. © Springer Publishing, 2007.]

second due to its relatively low cost and minimal human health risks.

When changes occur in the requirements or the decision process, decision analysis tools can respond efficiently to reprocess and iterate with the new inputs. The framework depicted in Figure 1 provides a focused role for the detailed scientific and engineering efforts invested in experimentation, environmental monitoring, and modeling that provides rigorous and defensible details for evaluating criteria of performances under various alternatives. This integration of decision tools and scientific and engineering tools allows each to have a unique and valuable role in the decision process without attempting to apply either type of tool beyond its intended scope.

The result of the entire process is a comprehensive, structured process for selecting the optimal

alternative in any given situation, drawing from stakeholder preferences and value judgments, as well as scientific modeling and risk analysis. This structured process would be of great benefit to decision making in environmental security management, where there is currently no structured approach for making justifiable and transparent decisions with explicit trade-offs between social and technical factors. The MCDA framework links heterogeneous information on causes, effects, and risks for different environmental policy options with decision criteria and weightings elicited from decision makers, allowing visualization and quantification of the trade-offs involved in the decision-making process. The proposed framework can also be used to prioritize research and information gathering activities and thus can be useful for the value of information analysis.

Environmental Tobacco Smoke

Background

Exposure to environmental tobacco smoke (ETS), also referred to as passive smoking, involuntary smoking, or secondhand smoke, has long been considered harmful. The US Surgeon General's report in 1972 [1] was one of the first governmental reports to recognize ETS as a health effect. The authors noted that animals exposed to tobacco smoke in laboratory experiments had a higher risk of respiratory cancers and there was evidence to suggest that acute respiratory illnesses were more common in children with parents who smoked.

Biological Plausibility

Approximately 85% of ambient tobacco smoke comes from the burning end of a lit cigarette between puffs (sidestream smoke). The rest is largely that exhaled by the smoker (mainstream smoke). Cigarette smoke contains over 4000 chemicals and exposure to ETS involves breathing in the same chemicals as active smoking but at a lower concentration. Active smoking is a cause of many fatal disorders including cancer, cardiovascular disease, and respiratory disease, as well as reproductive effects and chronic disorders such as cataracts, stomach ulcers, and hip fractures [2, 3].

Because of the dose–response relationship (*see Dose–Response Analysis*) between active smoking and each disorder, it is entirely plausible that a relatively little exposure (i.e., from ETS) will be associated with some risk of developing the same disorders. Examining markers of tobacco smoke intake in the urine, saliva, and blood of passive smokers supports this hypothesis. Nicotine is a substance that is, for practical purposes, only found in the environment in tobacco smoke. Nicotine and cotinine (a by-product of nicotine) are, therefore, useful markers of tobacco smoke inhalation and are sensitive enough to detect low concentrations. Studies show that these markers are two to three times greater in nonsmokers who report exposure to ETS compared to those who report no exposure [4], and that the concentration

increases with increasing exposure (Figure 1). Studies also show that cotinine and nicotine levels in passive smokers are, on average, about 1% of those seen in active smokers [4]. This is a nonnegligible level of exposure, which is expected to be associated with a nonnegligible level of risk. These biochemical studies confirm that tobacco smoke is inhaled and metabolized by nonsmokers in the same way as active smokers.

Health Effects in Adults

The first epidemiological studies, reported in 1981, focused on lung cancer [6, 7]. The two studies were based on lifelong nonsmokers and compared the incident rates of lung cancer in people married to smokers to those married to nonsmokers. Both showed an increased risk of lung cancer. Spousal exposure is a good measure of ETS because it is easily defined, validated (people married to smokers have higher concentrations of nicotine and cotinine), and it is a relatively stable measure since people tend to remain married for several years.

Many studies of ETS showed an increase in risk for various disorders, but most were not large enough to detect statistically significant associations on their own. Meta-analyses (*see Meta-Analysis in Nonclinical Risk Assessment; Meta-Analysis in Clinical Risk Assessment*) are a useful way of combining the quantitative information from all relevant studies to provide a more precise estimate of risk than any study on its own. A meta-analysis of 46 studies of ETS and lung cancer (Table 1) yields a 24% increase in risk. Adjustment for bias and potential confounding does not have a material effect on the estimate [8]. Other studies have looked at coronary (or ischemic) heart disease, chronic obstructive pulmonary disease (COPD), and stroke (Table 1). They too show a 25–30% excess risk. Although the main public health focus of ETS has been on lung cancer, the effect on the number of deaths from heart disease is greater because it is much more common than lung cancer in nonsmokers.

In the United States, in 2005 it was estimated that ETS caused 3400 lung cancer deaths among nonsmokers and 46 000 deaths from coronary heart disease – equivalent to about 5 deaths every hour [12]. In 24 countries of the European Union, about 19 240 nonsmokers were estimated to have died

Figure 1 Mean plasma cotinine (geometric mean and 95% confidence interval) in 8170 married or cohabiting nonsmokers according to the cigarette consumption of their partner [Reproduced from [5]. © BMJ Publishing Group, 2001.]

in 2002 from four disorders: lung cancer (1550), coronary heart disease (10 240), COPD (1170), and stroke (6280). This is equivalent to about two deaths every hour [13]. It should, however, be noted that these estimates from the United States and Europe are approximate and based on various assumptions associated with the prevalence of passive smoke exposure, the risk of developing each disorder, which were then used to apportion the total number of deaths in the population among nonsmokers and active smokers.

Although most of the evidence has been based on people who have never smoked, the effect of ETS on former smokers should not be ignored. The risk of death or chronic disease in smokers who quit rarely becomes the same as that of a never-smoker, and therefore the risk due to ETS when added to the risk associated with past smoking habits is an important consideration for ex-smokers. For example, the age-standardized rate of dying from lung cancer is 0.68

per 1000 among male ex-smokers and 0.17 per 1000 in never-smokers – a relative risk of 4 (0.68/0.17) [14]. Assuming ETS increases an ex-smoker's risk by 24% (as it does in never-smokers) the resulting death rate is 0.84 per 1000 – a relative risk of 5.

Health Effects in Children

A range of disorders in children and infants are caused by exposure to ETS. The main source of exposure investigated in studies has been parental smoking. Table 2 shows the odds ratio of having certain respiratory diseases or sudden infant death [2, 15]. The risk of a child suffering from lower respiratory illness (LRI) is 59% greater if either parent smoked compared to having two nonsmoking parents (odds ratio of 1.59). Other respiratory effects caused by ETS include middle ear effusion, asthma, cough, and wheeze. An even stronger association was found with sudden infant death, where infants were twice as likely to die early if their mother smoked. Consideration of confounding factors had little effect on the estimates of excess risk. In Table 2, the increase in risk tends to be higher with maternal smoking than paternal smoking reflecting the longer time spent with the mother during childhood, further supporting a causal link. The adverse effects on children are often overlooked when considering the public health impact of ETS, yet there is a clear effect on the health and quality of life during childhood if exposed to tobacco smoke at that time.

The Case for Banning Smoking in Public Places

Several countries already have some form of policy on restricting smoking in various environments,

Table 1 Health effects in adults caused by ETS (summary results from published meta-analyses)

Disorder	Number of studies in the meta-analysis	Total number of people with the disorder in the meta-analysis	Percentage increase in risk (95% CI) due to ETS
Lung cancer [9]	46	6257	24 (14–34)
Coronary heart disease [10]	19	6600	30 (22–38)
COPD [11]	8	1171	25 (10–43)
Stroke [4]	3	1147	27 (10–46)

CI, confidence interval

including the United Kingdom, California, New York, Ireland, Australia, and Italy. Many workplaces either do not allow it at all or have separate smoking rooms. In enclosed public places, while it is important to reduce or eliminate exposure to ETS among customers, the main justification behind a ban is the protection of workers. People who work in bars, clubs, and restaurants are often exposed to high levels of tobacco smoke for longer periods of time. Restrictions on smoking in these workplaces should, therefore, be in line with levels of protection in other areas of employment. The excess risk associated with ETS exposure in the hospitality industry is completely avoidable.

Epidemiology as Legal Evidence

In tort cases concerned with diseases resulting from exposure to a toxic chemical or drug, epidemiologic studies are used to assist courts in determining whether the disease of a particular person, typically the plaintiff, was a result of his or her exposure. This may seem puzzling to scientists, because whenever there is a natural or background rate of an illness one cannot be certain that its manifestation in a specific individual who was exposed to a toxic agent actually arose from that exposure. Indeed, the probability of causation in a specific individual is nonidentifiable [1]. The standard of proof that courts utilize in civil cases, however, is the preponderance of the evidence or the “more likely than not” criterion. Thus, scientific evidence that a particular agent can cause a specific disease or set of related diseases in the general population supports an individual’s claim that his or her disease came from their exposure. Conversely, scientific studies indicating no increased risk of a specific disease amongst exposed individuals are relied on by defendants, typically producers of the chemical or drug, to support the safety of their product. Studies relied on by experts testifying in cases are scrutinized intensely by opposing counsel for possible biases due to omitted covariates and measurement error or possible failure to consider the latency period before exposure and manifestation of the disease or inadequate power. Thus, it is important for scientists to be thoroughly prepared to discuss the relevant peer-reviewed literature before testifying. Similar questions of causation (*see* **Causality/Causation**) arise in cases alleging harm from exposure to hazardous wastes; although the issue in these cases is often whether the exposure was sufficient in magnitude and duration to cause the disease (*see* **Environmental Health Risk; Environmental Hazard**).

Epidemiologic studies are also used to determine eligibility for workers’ compensation, where the issue is whether the employee’s disease arose from exposure to an agent in the course of employment [2, p. 831], in regulatory hearings to determine safe exposure levels in the workplace (*see* **Occupational Cohort Studies**), and have even been submitted as evidence in criminal cases [3, p. 153]. We emphasize scientific evidence in tort law, which includes product

liability and mass chemical exposure cases, because it is the major area of the law utilizing epidemiologic studies as evidence.

Tort Law

Tort law generally concerns suits for wrongful injury that do not arise from a contract between the parties. Thus, remedies to compensate for injuries from a wide variety of accidents resulting from someone’s negligence, e.g., professional malpractice, assault and battery, environmentally induced injury, and fraud can be obtained by a successful plaintiff. Product liability is a special area of tort law dealing with the obligations of manufacturers of products to consumers who may suffer personal injury arising from the use of the product.

In any tort claim the plaintiff needs to establish a *prima facie* case by showing that the defendant has a legal duty of care due to the plaintiff and that the defendant breached that duty. In addition, a plaintiff needs to show that (a) he/she suffered an injury and that the defendant’s failure to fulfill its duty of care was the (b) factual and (c) legal cause of the injury in question. The law also recognizes defenses that relieve the defendant of liability. The two most prominent ones in tort suits are contributory negligence by the plaintiff and statutes of limitations, which bar suits that are brought after a specified period of time has elapsed from either the time of the injury or the time when the relationship between the injury and the use of the product was known to the plaintiff [4]. In some jurisdictions, especially in Europe [5, p. 834], if the injury results from a defect arising from the product’s compliance with a mandatory legal provision at the time it was put on the market, then the manufacturer is not liable. There are substantial differences between jurisdictions as to whether a plaintiff’s contributory negligence totally absolves the defendant from liability, reduces it in proportion to the relative fault of the parties, or has no effect on the liability of a defendant whose contribution to the injury was small. In the United States, the plaintiff’s fault is rarely a complete bar to recovery when the defendant’s negligence had a significant role. Similarly, the effective starting date of the limitations period varies among nations and among the states in the United States.

When reading actual legal cases that rely on scientific evidence, one needs to be aware of the relevant

legal rules. For example, although the epidemiologic evidence linking the appearance of a rare form of vaginal cancer in a young woman to her mother's use of diethylstilbestrol during pregnancy is quite strong [6], some states barred plaintiffs from suing because the statute of limitations had expired. Since the cancers were recognized only when the young women passed puberty, typically in the late teens or early twenties, a number of injured women could not receive compensation. Other states, however, interpreted the limitations period as beginning at the time the plaintiff should have been aware of the connection. In Europe, the European Economic Community (EEC) directive of 1985 provides for a 10-year statute of limitations and allows plaintiffs to file claims within 3 years after *discovering* the relationship. Markesinis [5] summarizes the directive and the relevant English and German laws.

In fact epidemiologic evidence is most useful in resolving the issue of cause, i.e., whether exposure to the product made by the manufacturer or chemicals spilled onto one's land by a nearby company can cause the injury suffered by the plaintiff. An alternate formulation of the factual cause issue is whether exposure increases the probability of contracting the disease in question to an appreciable degree. Case-control studies (*see Case-Control Studies*) were used for this purpose in the litigation surrounding Rely and other highly absorbent tampons [2, p. 840]. Within a year or two after these products were introduced, the incidence of toxic shock syndrome (TSS) among women who were menstruating at the time of the illness began to rise sharply. Several studies, cited in Gastwirth [2, p. 918], indicated that the estimated relative risk (*see Relative Risk*) of contracting the disease for users of these tampons was at least 10, which was statistically significant.

In light of the sharp decline in the incidence of TSS after the major brand, Rely, was taken off the market, the causal relationship seems well established and plaintiffs successfully used the studies to establish that their disease was most likely a result of using the product. When only one case-control study, however, indicates an association between exposure and a disease, courts are less receptive. Inskip [7] describes the problems that arose in a British case concerning radiation exposure of workers and leukemia in their children, and Fienberg and Kaye [8] discuss general issues concerning the information provided by clusters of cases.

There is a rough rule relating the magnitude of the relative risk, R , of a disease related to exposure and the legal standard of preponderance of the evidence, i.e., at least half of the cases occurring amongst individuals exposed to the product in question should be attributable to exposure. As the attributable risk is $(R - 1)/R$, this is equivalent to requiring a relative risk of at least 2.0. While a substantial literature discusses this requirement (see [9, pp. 1050–1054], [2, Chapters 13 and 14], [10], and [11, pp. 167–170] for discussion and references), some courts have been reluctant to adopt it formally [12], since it would allow the public to be exposed to agents with relative risks just below 2.0 without recourse. The author found the lowest value of R accepted by a court to be 1.5, in a case concerning the health effects of asbestos exposure. Courts usually require that the estimated R be statistically significantly greater than 1.0 and have required a confidence interval for R but also consider the role of other error rates [11, pp. 153–154]. When a decision must be based on sparse evidence, courts implicitly consider the power of a test and may not strictly adhere to significance at the 0.05 level.

The relative risk estimated from typical case-control studies is taken as an average for the overall population. Courts also consider the special circumstances of individual cases and have combined knowledge of the prior health of a plaintiff, the time sequence of the relevant events, the time and duration of exposure, as well as the latency period of the disease, with epidemiologic evidence to decide whether or not exposure was the legal cause of a particular plaintiff's disease. The different verdicts concerning the manufacturer in the cases of Vioxx, a Cox-2 pain reliever shown to increase the risk of cardiovascular problems, may be due to the substantial variability in the other risk factors and general health of the plaintiffs.

So far, our discussion has dealt with the criteria for factual causality where an injury has already occurred. In some cases concerning exposure to a toxic chemical, plaintiffs have asked for medical monitoring, such as periodic individual exams or a follow-up study. As this is a new development, a specific minimal value of R has not been established. Recently, the Supreme Court of Missouri in *Meyer v. Fluor Corp.* No. SC8771 (2007) allowed a class action on behalf of children exposed to lead from a smelting facility to proceed. The opinion

sided with jurisdictions that have held that a plaintiff can obtain damages for medical monitoring when they have significantly increased risk of contracting a particular disease as a consequence of their exposure.

In product liability law, a subclass of tort, in addition to negligence claims, sometimes one can assert that the manufacturer is subject to strict liability [13, 14]. In strict liability the test is whether the product is unreasonably dangerous, not whether the manufacturer exercised appropriate care in producing the product. Epidemiologic studies indicating a substantial increased risk of a disease can be used to demonstrate that the product is “unreasonably dangerous” from the viewpoint of the consumer.

An increasing number of product liability cases concerns the manufacturer’s duty to warn of dangers that were either known to the manufacturer or could reasonably have been foreseen at the time the product was marketed. In the United States, producers are also expected to keep abreast of developments after the product is sold and to issue a warning and possibly recall the product if postmarketing studies show an increased risk of serious disease or injury.

One rationale underlying the duty to warn is informed consent [15, p. 209] (*see Randomized Controlled Trials*). Because asbestos was linked to lung cancer by a major study [16] published in the 1960s, the plaintiff in *Borel v. Fibreboard Paper Products Corp.*, 493 F. 2d 1076 (5th Cir. 1973) prevailed on his warning claim. The opinion observed that a duty to warn arises whenever a reasonable person would want to be informed of the risk in order to decide whether to be exposed to it.

The time when the risk is known or knowable to the manufacturer is relevant. In *Young v. Key Pharmaceuticals*, 922 P. 2d 59 (Wash. 1996), the plaintiff alleged that the defendant should have warned that its asthma drug increased the risk of a seizure. The firm argued that the studies existing in 1979, when the child was injured, were not clinically reliable. Even though subsequent research confirmed those early studies that suggested an increased risk, the court found that the defendant did not have a duty to warn in 1979.

The reverse situation may have occurred in the *Wells* case, 788 F. 2d 741 (11th Cir. 1986). At the time the mother of the plaintiff used the spermicide made by the defendant, two studies had shown

an increased risk of limb defects and the court found the firm liable for failing to warn. Subsequent studies, which still may not be definitive, did not confirm the earlier ones, and in a later case the defendant was found not to be liable. While this seems inconsistent from a scientific point of view, from a legal perspective both decisions may be reasonable because the information available at the two times differed. A review of the studies and reports discussed in the *Wells* and *Young* decisions is given in Gastwirth [17] where an ethical issue in conducting follow-up studies of the relationship of spermicide use while pregnant and birth defects is noted. Once a woman is pregnant, asking her to use any product that might harm the child is unethical, so one cannot conduct a controlled clinical trial, randomly assigning females to continue to use or not use a spermicide.

The legal issues involved in warning cases are quite involved and differ among the states in the United States. Some states have a learned intermediary rule, which absolves the manufacturer of liability if it warns the medical community and the treating doctor would not have changed his/her decision to prescribe the drug. The decision in *Madsen v. American Home Products Corp.* (E.D. Mo. No. 02–1835, 2007) noted that although the firm knew about the risk it did not adequately warn consumers or the medical community about the risk of heart valve disease associated with two diet drugs as reported in studies in 1993 and case reports in 1994–1996 showed the firm knew about the risk. However, the plaintiff needed to show that the warning would have affected either the doctor’s prescription or her decision to take them. As the doctor continued to prescribe the drug after the medical community was notified of the risk in mid-1997 and as the plaintiff never read any material about the drugs, an earlier warning would not have prevented her illness. In *Petty v. U.S.*, 740 F.2d 1428 (1984), which concerned an illness contracted in the context of a mass immunization where there was no learned intermediary, the producer, however, had the responsibility to warn the ultimate consumer.

The increased media advertising of drugs directly to consumers has generated complaints of misleading advertising, especially when the drug is marketed for an off-label use, i.e., for treating a different ailment than it was approved for by the authorities. In 1996, Zyprexa was approved for treating

schizophrenia and bipolar disorder and the producer apparently informed the psychiatric community of risks associated with its use. Recently, several other states including Montana have filed suits accusing of the manufacturer of misleading advertising as it marketed the drug for treating other problems, e.g., anxiety and depression rather than psychotic conditions it was approved for without adequately informing patients or their primary care physicians of known increased risks for strokes, heart attacks, and pancreatic disorders.

Government Regulation

Epidemiologic studies are used by regulatory agencies such as the Food and Drug Administration (FDA) and Occupational Safety and Health Administration (OSHA) to get manufacturers to recall harmful products or give an appropriate warning. Indeed, the manufacturer of Rely tampons recalled the product after the fourth case-control study linked it to TSS. More recently, case-control studies supported a warning campaign.

In 1982, after a fourth study indicated an association between aspirin use and Reye's syndrome, the FDA proposed a warning label on aspirin containers. The industry challenged the original studies, and the Office of Management and Budget (OMB) asked the FDA [18, 19] to wait for another study. The industry suggested that caretakers of cases would be under stress and might guess aspirin, especially if they had heard of an association, so two new control groups (children hospitalized for other reasons and children who went to an emergency room) were included in the follow-up study [20]. The odds ratios (OR) (*see Odds and Odds Ratio*) for cases compared with each of these two control groups were about 50, far exceeding those of the school ($OR = 9.5$) and neighborhood controls ($OR = 12.6$).

In late 1984 the government, aware of these results, asked for a voluntary warning campaign; a warning was mandatory as of June 1986. The following are the Reye's syndrome cases and fatalities from 1978 to 1989: 1978 (236, 68); 1979 (389, 124); 1980 (555, 128); 1981 (297, 89); 1982 (213, 75); 1983 (198, 61); 1984 (204, 53); 1985 (93, 29); 1986 (101, 27); 1987 (36, 10); 1988 (25, 11); and 1989 (25, 11). The cases are graphed in Figure 1. Notice the sharp decline between 1983-1984 and 1985-1986, which resulted from the warning campaign.

Criteria for Admissibility of Testimony Relying on Epidemiologic Studies as Evidence

Courts are concerned with the reliability of scientific evidence, especially as it is believed that lay people may give substantial weight to scientific evidence. In the United States, the *Daubert* decision, 113 US 2786 (1993), set forth criteria that courts may use to screen scientific evidence before it goes to a jury. The case concerned whether a drug, Bendectin, prescribed for morning sickness caused birth defects, especially in the limbs. Related cases and the studies are described at length in Green [21]. The *Daubert* decision replaced the *Frye* 293 F. 1013 (DC Cir. 1923) standard, which stated that the methodology used by an expert should be "generally accepted" in the field by the criteria in the Federal Rules of Evidence. The court gave the trial judge a gate-keeping role to ensure that scientific evidence is reliable. Now judges must examine the methodology used and inquire as to whether experts are basing their testimony on peer-reviewed studies and methods of analysis before admitting the evidence at trial. Several commentators, e.g., Kassirer and Cecil [22] have noted that there is substantial variability in the way lower courts apply the *Daubert* criteria when they evaluate expert reports and prospective testimony.

The US Supreme Court decision in *Daubert* remanded the case for reconsideration under the new guidelines for scientific evidence. The lower court, 43 F. 3d (9th Cir. 1995), decided that the expert's testimony did not satisfy the *Daubert* guidelines for admissibility in part because the plaintiff's expert never submitted the meta-analysis (*see Meta-Analysis in Clinical Risk Assessment*) of several studies, which was claimed to indicate an increased relative risk, for peer review. Similarly, in *Rosen v. Ciba-Geigy*, 78 F. 3d 316 (7th Cir. 1996), the court excluded expert testimony that a man's smoking while wearing a nicotine patch for 3 days caused a heart attack. The appeals court said that the expert's opinion lacked the scientific support required by *Daubert* because no study supported the alleged link between short-term use of the patch and heart disease caused by a sudden nicotine overdose. The *Rosen* opinion notes that the trial judge is not to do science but to ensure that when scientists testify in court they adhere to the same standards of intellectual rigor they use in their professional work. If they

do so and their evidence is relevant to an issue in the case, then their testimony is admissible, even though the methods used are not yet accepted as canonical in their branch of science.

In two opinions that followed *Daubert*, *Joiner v. General Electric*, 522 U.S. 136 (1997), and *Kumho Tire Co. v. Carmichael*, 119 S.Ct. 1167 (1999), the Court expanded the trial judge's role in screening expert testimony for reliability. Now, testimony relying on studies from social science and technical or engineering experience will be subject to review by the judge before the expert is allowed to testify. The *Kumho* opinion noted that the factors mentioned in *Daubert* (e.g., whether the theory or technique on which the testimony is based has been tested, whether it has been subject to peer review and publication, the known or potential error rate) were only a guideline rather than criteria to be strictly applied to prospective

expert testimony. In particular, the circumstances of the particular case will have a major role. Commentators [23–26]) have discussed its implications as well as cases where the circuit courts (covering different regions of the United States) have disagreed in their evaluations of similar evidence. Fienberg *et al.* [27] and Loue [28] discuss the reviewing process, noting some important factors for judges to consider.

The *Chapin v. A & L Parts, Inc.* (Ct. of Appeals, MI 2007) opinion provides an instructive discussion of the factors courts use in assessing the reliability of expert testimony on scientific studies. Although a number of epidemiologic studies had not found an increased risk of mesothelioma in workers handling brake parts due to possible exposure to asbestos, plaintiff's expert noted that the populations studied included workers who had less exposure than the plaintiff (who ground brake linings in his job as a

Figure 1 The number of cases of Reye's syndrome for the years 1978–1989

brake mechanic). He also noted that some studies had not allowed sufficient time (latency period) for the disease to manifest itself, while others were of limited sample size and lacked power to detect a moderate increased relative risk. Because the other criteria in the guidelines suggested by Sir Bradford Hill [29] were met and the disease is known to be highly related to asbestos exposure, he asserted that it was more likely that the plaintiff's case was caused by asbestos exposure. The defense expert apparently stated that causation could only be established by well-controlled epidemiological evidence and that case reports and other studies, e.g., animal and toxicological, were insufficient. Usually courts give much greater weight to epidemiologic studies of human populations; however, the plaintiff's expert provided a sound explanation of their deficiencies. This suggests that statistical methods for assessing the potential impact of omitted variables and other problems that inevitably occur with observational studies (Rosenbaum [30]) may have a more important role in the future. Usually these methods are used to explore whether a statistical association suggesting an increased risk of an illness can be plausibly explained by an omitted variable or other flaw; however, they can also be used to examine whether another risk factor that is more prevalent in the control group could mask a true increased risk (Yu and Gastwirth [31]).

In contrast to *Chapin*, when an expert simply relies on the temporal relationship between exposure to a drug or chemical and the subsequent development of an impairment, which may be caused by other factors, the testimony was deemed inadmissible. This occurred in *Salden v. Matrixx Initiatives* (E.D. Mich. No. 06–10277, 2007) where the expert had not performed any tests nor referred to other tests or studies published by other scientists.

Recently, in *Knight v. Kirby Inland Marine Inc.* (5th Cir. 2007), the court upheld a lower court's decision to exclude expert testimony in a maritime toxic tort suit because the court concluded that the studies relied upon by the expert failed to give an adequate basis for the opinion that the types of chemicals that the plaintiffs were exposed to in their marine employment can cause their particular injuries in the general population. The trial judge concluded that many of the studies the expert relied on had focused on several chemical exposures rather than on benzene, the chemical the plaintiffs had been

exposed to, and that some of the other studies were not statistically significant. The appellate opinion also reviews other relevant legal cases concerning the broad leeway trial judges have in performing their gate-keeping role.

Courts have reached different conclusions concerning the admissibility of the method of differential diagnosis, where medical experts conclude that a disease was caused by a particular exposure by eliminating other potential causes. The cases concerning the drug Parlodel and its relationship to stroke, discussed in [17], illustrate the problem. After studies showed that the drug could cause ischemic strokes, some plaintiffs offered expert testimony that these studies showed the drug could cause hemorrhagic strokes too. The *Rider v. Sandoz*, 295 F.3d 1194 (11th Cir. 2002) opinion upheld a lower court's rejection of this extrapolation. At the same time it cited favorably *Globetti v. Sandoz* (111 F. Supp. N.D. Ala 2001), which admitted testimony based on differential diagnosis, and also stated that epidemiologic studies are not an absolute requirement. While no human studies had been carried out, animal studies had indicated a risk. The expert was allowed to utilize this information in a differential diagnosis. Thus, the trial judge's assessment of the care and thoroughness with which a differential diagnosis or other scientific study has been carried out by a prospective expert as well as whether the expert has considered all other relevant evidence that is available at the time will be a major factor in deciding whether the testimony is admissible.

JOSEPH L. GASTWIRTH

Equity-Linked Life Insurance

In equity-linked life insurance contracts, the benefits are directly linked to the value of an investment portfolio. This portfolio is typically composed of units of one or more mutual funds (also called *unit trusts*, in some countries), and is kept separate from the other assets of the insurance company. That is why in Canada it is usually referred to as *segregated fund*. It can be directly managed by the insurance company, although an independent management is very common. In particular, even if the term *equity-linked* clearly applies to an investment portfolio mainly composed of equities, it can also be interpreted in a broad sense and concerns all life insurance contracts in which benefits are not (totally) expressed in units of the usual domestic currency but in units of a given asset that can be, e.g., a stock, a stock index, a mutual fund, a foreign currency, a commodity, etc. The same contracts are also referred to as *unit-linked*, or *variable life* in the United States.

Then the distinguishing feature of equity-linked contracts with respect to traditional nonparticipating policies is that the cash value of benefits is stochastic (see **Stochastic Control for Insurance Companies**). Also the premiums could be expressed in units of the reference asset, although this is rather unusual. Premiums, net of insurance and expense charges, are deemed to be invested in the reference asset, i.e., used to buy units of this asset that are credited to a separate account called *unit account* of the policyholder. Note that it is not necessary that such investments are actually made, although this could be required by regulations. In any case the number of units deemed to be acquired up to a given time defines the reference portfolio to which benefits are linked. Partial withdrawals from the unit account are sometimes allowed, as well as early surrender, which however is usually penalized.

Equity-linked policies are generally characterized by a high level of financial risk. This risk can be totally charged to the policyholder, in *pure equity-linked contracts*, or it can be shared between the policyholder and the insurance company, in *guaranteed equity-linked contracts*. In the first case the insurance company acts as a mere financial intermediary, and bears neither investment nor mortality risk

if it actually invests the premiums (net of expense charges) in the reference asset. Minimum guarantees are often offered in case of death and sometimes also in case of survival. The minimum guarantee is usually a fixed amount, possibly time dependent. This amount can be related to the total premiums paid or to the part of them deemed to have been allocated in the reference fund. In particular it can be equal to a percentage, ≤ 100 , of these premiums, with or without accrued interests at a minimum interest rate guaranteed. Both in case of death and in case of survival, the guarantees can operate only when benefits become due (*terminal guarantees*) or year by year (*annual* or *cliquet guarantees*). Obviously, annual guarantees are much riskier than terminal ones from the insurance company's point of view, and hence they could require a too high cost. There are also other kinds of guarantees more or less "exotic", e.g., they can contain a *reset* feature, etc.

Compared with traditional life insurance contracts, the main advantage of equity-linked policies from the policyholder's point of view resides in the fact that he/she can directly determine his/her investment strategy, i.e., choose the particular assets to which the policy is being linked and, often, change them during the life of the contract (*switching option*). Moreover, there could be also a certain flexibility in the choice of the periodic premium amounts, as in *Universal Life Insurance*. Last, but not least, there is more transparency about the returns on the policyholder's account as well as about the charging structure, and there are no elements of uncertainty introduced by the discretionary powers of the insurance company in setting bonuses. Compared with a direct investment in a mutual fund, the policyholder can benefit from a more favorable tax treatment, in particular tax relief is often available on the premiums (see **Longevity Risk and Life Annuities**).

The Development of the Unit Account

Consider an equity-linked contract issued at time 0. Assume that this contract is a whole life assurance, or an endowment policy, or a deferred annuity with a death benefit. In the last two cases, we denote the maturity date or the end of the accumulation period, respectively, by T . Assume that the contract is paid by a sequence of fixed (or flexible) premiums $\{P_t\}$, due at predetermined dates t (e.g., beginning of each

year, or beginning of each month, until death or until time T , whichever comes first). Note that in case of single premium contracts, P_0 represents the single premium and $P_t = 0$ for any $t > 0$. Assume, at least for the moment, that the contract is a pure equity-linked one; hence, it offers no kind of guarantees and the value of the unit account of the policyholder will be totally paid at death or maturity, or converted into a life annuity at the end of the accumulation period according to the current market conditions.

As already said, only a part of the premium P_t is deemed to be invested in the reference asset. If we denote the allocation rate by α_t (≤ 1), the amount $\alpha_t P_t$ is used to buy units of this asset that are credited to the unit account. These units are bought at the *offer price*, which at any time t is about 5% greater than the corresponding *bid price*, i.e., the price at which units are converted (“sold back”) in order to make benefit payments or expense deductions. Then the difference between offer and bid price, called *bid-offer spread*, compensates the insurance company for transaction costs incurred in buying and selling units of the reference asset. The nonallocated premium $(1 - \alpha_t)P_t$ is used to recover expenses, in particular initial and premium collection expenses.

Possible income distributions from the assets composing the reference portfolio are usually reinvested. This implies the purchase of additional units at the offer price, which are credited to the unit account. The cash value of this account at any time t , also called *face value*, is given by the number of units multiplied for the bid price.

At regular intervals, e.g., every month, charges for administrative expenses are deducted from the unit account. This implies the cancelation of a certain number of units at the bid price in order to recover such expenses, which are usually expressed as a fixed amount, possibly time dependent (e.g., linked to a price index). Moreover, also a fund management charge, expressed as a percentage of the face value of the unit account (commonly in the range 0.25–1%), is deducted by canceling units at the bid price.

All unallocated premiums, as well as all charges deducted from the unit account or deriving from the bid-offer spread, constitute another reserve, called *nonunit account* (or *sterling account*, in the United Kingdom), which could also be negative (see **Premium Calculation and Insurance Pricing**). Note

that the value of this account is not so transparent to the policyholder as that of the unit account. In fact it behaves like the reserves backing traditional, nonlinked, business.

Till now we have considered a pure equity-linked contract that works exactly as a financial investment plan. Then, as already said, the insurance company bears no kind of risk (provided that charges for expenses are appropriate). Instead if we consider a guaranteed contract, in which the death benefit is fixed or there is a minimum guarantee at death or maturity, there are additional charges, called *insurance* or *risk charges*, that increase the nonunit reserve. These charges are given by the risk premium for (possible) *nonunit benefits* that will be deducted from the nonunit reserve, when due. In case of periodic premiums the insurance charges imply a decrease of the allocatable amount $\alpha_t P_t$ (if sufficient), while in case of paid-up policies it is very common to make regular deductions from the unit account, as for administrative and fund management charges, i.e., to transfer funds from the unit to the nonunit account.

The nonunit death benefit is given by the *sum at risk*, i.e., by the difference between the death benefit and the face value of the unit account. This difference could also be negative when the death benefit is fixed, and in this case the mortality “charge” could involve a transfer of funds from the nonunit to the unit account. However, if there is a minimum death guarantee, the sum at risk is never negative and can be seen as the payoff of a put option with underlying variable being the face value of the unit account and exercise price being the minimum amount guaranteed (see **Optimal Stopping and Dynamic Programming**).

Insurance charges are also applied when there are minimum guarantees in case of survival. As far as non-unit survival benefits are concerned, note that they are not necessarily related to the presence of survival guarantees. In fact they can arise also if no benefits are actually paid, and in this case they imply a transfer of funds from the nonunit to the unit account. This happens, e.g., when a cliquet guarantee becomes effective, because the face value of the unit account at the end of each year cannot be less than the corresponding annual guarantee settled at the beginning of the year.

To sum up, we represent, in what follows, the evolution of the unit account in the generic time interval $[t, t + 1]$ (during the accumulation period, if

a variable annuity is dealt with). We assume that there are no movements of units between t and $t + 1$ and that premiums (if any) are collected (and allocated) at the beginning of the interval, as well as insurance and administrative charges, while fund management charges and (possible) income distributions or transfers of funds due to nonunit survival benefits are made at the end of the interval. Of course, if there are no premiums, or transfers, or income distributions, the corresponding variables are set equal to 0. In particular, as for insurance charges, we assume that (part of) administrative charges are deducted from the unit account, at the bid price, only if the amount deemed to be allocated in the reference fund $\alpha_t P_t$ is not sufficient, otherwise they are directly deducted from this amount before the purchase of new units at the offer price.

Besides the variables α_t and P_t already introduced, we denote by n_τ the number of units of the unit account at time τ ($\tau = t, t + 1$), after deductions for fund management charges, transfer of funds for nonunit survival benefits, income distribution and consequent reinvestment, and before payment and premium allocation, as well as before insurance and administrative charges; F_{t+1} is the face value of the unit account at time $t + 1$, O_τ (respectively B_τ) the offer (bid) unit price at time τ ($\tau = t, t + 1$), I_t the insurance charge, A_t the charge for administrative expenses, f_{t+1} the rate of fund management charge, D_{t+1} the distributed income, and S_{t+1} the nonunit survival benefits transferred from the nonunit to the unit account.

We then have,

$$\begin{aligned} n_{t+1} = n_t + & \frac{\max\{\alpha_t P_t - I_t - A_t, 0\}}{O_t} \\ & - \frac{\max\{I_t + A_t - \alpha_t P_t, 0\}}{B_t} \\ & - f_{t+1} n_{t+1} + \frac{S_{t+1}}{B_{t+1}} + \frac{D_{t+1}}{O_{t+1}} \end{aligned} \quad (1)$$

from which

$$\begin{aligned} n_{t+1} = & \frac{1}{1 + f_{t+1}} \left[n_t + \frac{\max\{\alpha_t P_t - I_t - A_t, 0\}}{O_t} \right. \\ & - \frac{\max\{I_t + A_t - \alpha_t P_t, 0\}}{B_t} \\ & \left. + \frac{S_{t+1}}{B_{t+1}} + \frac{D_{t+1}}{O_{t+1}} \right] \end{aligned} \quad (2)$$

and

$$F_{t+1} = n_{t+1} B_{t+1} \quad (3)$$

Note that the number of units bought with the nonunit survival benefits is credited at the bid price, because the amount of such benefits has to correspondingly increase the face value of the unit account, computed at the bid price.

The face value of the unit account is then entirely paid in case of death or survival at maturity, or its units are transformed into units of a paid-up annuity at the end of the accumulation period. In case of surrender it is usual to pay back this value after the application of a surrender penalty. Any other payments deriving from minimum guarantee provisions are instead made by the nonunit account.

Hedging Strategies for Nonunit Benefits

We have seen, in the previous section, that if the unit account is not only a notional portfolio but the real investment reserve backing the policy under scrutiny, then the (residual) liabilities that the insurance company has to hedge are given by the nonunit benefits. These benefits are null in pure equity-linked contracts, while they are always non-negative in guaranteed (uncapped) contracts.

To fix the ideas, consider the endowment policy and assume that in case of death during a given year of contract, the benefit is paid at the end of the year. Assume that the contract provides some terminal minimum guarantees at death and/or survival at maturity. We denote the minimum amount guaranteed in case of death during the t th year of contract by G_t^D , $t = 1, 2, \dots, T$, and the minimum amount guaranteed in case of survival at maturity by G_T^S . These amounts are assumed to be fixed at inception. In particular, if $G_t^D = 0$ for any t there are no minimum death guarantees, while if $G_T^S = 0$ there are no survival guarantees.

Then the stream of liabilities of the insurance company due to nonunit death benefits, $\{L_t^D\}_{t=1}^T$, is given by

$$\begin{aligned} L_t^D = & \max\{G_t^D - F_t, 0\} \mathbb{I}_{[t-1 < T_x \leq t]}, \\ & t = 1, 2, \dots, T \end{aligned} \quad (4)$$

where T_x denotes the remaining lifetime of the insured (with entry age x) and $\mathbb{I}_{\{\mathcal{E}\}}$ the indicator function of the event $\mathcal{E}$, equal to 1 if $\mathcal{E}$ is true and 0 otherwise. Moreover, since we are dealing with terminal guarantees, there is only one nonunit survival benefit that will be paid in case of survival at maturity; hence, the corresponding liability is given by

$$L_T^S = \max\{G_T^S - F_T, 0\} \mathbb{I}_{\{T_x > T\}} \quad (5)$$

All these liabilities are clearly dependent on both mortality and financial risk. In particular, they can be seen as the payoff of a (single) put option with underlying variable being the face value of the unit account (as already said), time-dependent exercise price (and possibly also survival-dependent, if $G_T^D \neq G_T^S$), and stochastic exercise date. Taking into account that this date is not chosen by the option holder, as in the case of American options, but is triggered by an event, the death of the insured, which can be reasonably assumed to be independent of the behavior of financial markets, such an option is something in between European and American styles; that is why Milevsky and Posner called it *Titanic option* (see [1]).

However, if the mortality risk is diversified away because the insurance company is able to sell enough contracts in order to eliminate the fluctuations between actual and expected mortality rates, this Titanic option can be replaced by a portfolio of European options with different maturities $t = 1, 2, \dots, T$ and payoff stream given by

$$\begin{cases} \tilde{L}_t^D = \max\{G_t^D - F_t, 0\} {}_{t-1|}q_x, & t = 1, 2, \dots, T \\ \tilde{L}_T^S = \max\{G_T^S - F_T, 0\} {}_T p_x \end{cases} \quad (6)$$

where the standard actuarial symbol ${}_{t-1|}q_x$ denotes the probability that the insured dies during the t th year of contract, and ${}_T p_x$ the probability that he/she is still alive at the maturity date. Then the simplest approach to hedge the liabilities since inception is undoubtedly that of transferring them to a third party, i.e., to buy the put options in the market, if traded, or from a reinsurer. However, due to the long-term nature of life insurance business, it is very unlikely that these options are traded. When this approach is not viable either because no options on the reference fund are available, even if issued by a reinsurer, or because they would require a too

high cost, the insurance company has to directly hedge its liabilities with investments in the available assets, typically bonds and units of the reference portfolio.

We observe that even if the analysis of equity-linked life insurance policies from an “actuarial” point of view was a “hot” topic that attracted the interest of many actuaries since the issue of the first contracts in the beginning of the second half of the twentieth century, Boyle, Brennan, and Schwartz were the first who recognized that a guaranteed benefit can be decomposed in terms of European options, once the mortality risk is diversified away, in their pioneering work of the mid-1970s (see [2–5]), and applied to them on the then recent results on option pricing theory initiated by Black, Merton, and Scholes at the beginning of the same decade (see [6, 7]). In particular, Boyle, Brennan, and Schwartz analyzed an equity-linked endowment policy (which we are considering here) in an idealized framework in which insurance and financial markets are perfectly competitive and frictionless, free of arbitrage opportunities, and trading takes place in continuous time. Hence they did not take into account transaction costs and consequent bid–ask spread, at least in a first moment, as well as expenses and relative charges. Moreover, they assumed no dividend distributions from the assets composing the reference portfolio.

In such a framework, characterized by complete financial markets, the payoff of any contingent claim and hence also that of European put options can be perfectly replicated by means of a dynamic self-financing hedging strategy in riskless bonds and underlying asset. This strategy, also called *risk-neutral strategy*, involves continuous rebalancing of the hedging portfolio at no cost (and no proceeds). In particular, the hedging of a put option requires to shortsell a certain quantity of underlying asset given by the partial derivative (“sensitivity”) of the option price with respect to the price of the same asset. Then, since the risk-neutral strategy allows to perfectly replicate the final payoff of the option without requiring additional money (apart from that required to set it up), to prevent arbitrage opportunities the price of the option must be given by the initial cost of the strategy. It can be shown that this price is expressible as the expectation, under a suitable probability measure called *risk-neutral measure*, of

the final payoff of the option discounted with the rate of return on risk-free assets. To sum up, in this framework the “fair” insurance charges are given by the expectation, under the risk-neutral measure, of all nonunit liabilities $\{\tilde{L}_t^D\}_{t=1}^T$ and $\tilde{L}_T^S$ discounted with the risk-free rate (see **Statistical Arbitrage**).

Unfortunately, the risk-neutral strategy just described requires a continuous rebalancing of the hedging portfolio, but trading in the “real world” is not time-continuous and, moreover, the real world is affected by transaction costs that could make very frequent rebalancing prohibitive. Then there is a trade-off between the frequency of rebalancing in a discrete setting (that determines the “hedging error”) and transaction costs. For this reason Brennan and Schwartz in [4, 5] analyze discrete approximations of the perfect (risk-neutral) hedging strategy by taking transaction costs into account and assuming that rebalancing takes place either at regular intervals or when the hedging error (absolute or relative) exceeds a given threshold. We remark that since the hedging of nonunit benefits would require the short sale of the reference asset, in order to reduce transaction costs it is better to hedge the total liabilities (unit + nonunit part) as a whole and, hence, keep investments in the reference asset less than those defining the unit account of the policyholder.

Another approach to hedge the nonunit benefits, called sometimes the *actuarial approach*, consists in projecting, by means of a stochastic simulation model, the future liabilities of the insurance company and keeping investments in risk-free assets sufficient to meet them with a “high” probability. The initial cost required by this value-at-risk (VaR)-based approach, pioneered in [8], is generally higher than that required by the risk-neutral one, but there is a high probability that the value of the hedging portfolio turns out to be greater than the liabilities when the contract expires, and hence that money can be recovered back by the insurance company. However, if the reference portfolio exhibits an extremely bad performance, this approach can lead to high losses. For further details see [9, 10].

So far we have assumed that the mortality risk is diversified away. If this is not the case, i.e., if the insurance company does not sell enough contracts and/or there is a systematic part of mortality risk that affects all policies in the same direction, then we cannot replace the Titanic option with a portfolio of European options and hence reduce

ourselves to hedge purely financial contingent claims in a complete market. In this case the insurance company has to hedge an *integrated risk*, depending on both mortality and financial uncertainty, in a typically incomplete market, where not all claims are replicable. This implies the choice of a particular *risk-minimizing* hedging strategy, which can be followed also in case of diversifiable mortality risk when the financial market is however incomplete. For an analysis of these risk-minimizing strategies, we refer to the work by Møller (see [11–14]).

To conclude, we observe that the same philosophy presented here with reference to the hedging of terminal guarantees can be applied to the case of cliquet guarantees. In fact, also in this case the nonunit benefits can be expressed as the payoff of put options, although with exercise price not known at inception but only at the beginning of each year of contract. Then it is more appropriate to set up suitable hedging strategies for them at the beginning of each year, rather than directly at inception. This is also in line with the practice (described in the previous section) of making regular deductions from the unit account for insurance charges even in the case of single premium contracts.

ANNA R. BACINELLO

Estimation of Mortality Rates from Insurance Data

Mortality rates are instrumental in life insurance. These rates form the basis for pricing of insurance products and determination of reserves for a life insurance company. They also can be used to determine other functions within a life table (*see Insurance Applications of Life Tables*), such as the life expectancy (*see Longevity Risk and Life Annuities*) and survival rates. Consequently the determination of these rates from data in life insurance studies plays a very important role in the actuarial profession.

Within the Society of Actuaries in the United States of America, intercompany data on insurance policies issued to standard lives (policies issued to lives that were judged as “healthy” when the insurance policy was issued) resulted in the 1965–1970 [1] and the 1975–1980 basic mortality tables [2]. More recent studies [3] are based on the Society of Actuaries 1995–2000 mortality study.

This paper is split into four parts. The first part defines the mortality rates that are pertinent in life insurance. The second part discusses the estimation of these mortality rates from intercompany insurance data. The third part discusses the methods used in determining rates for ages not available, called *interpolation*, and the smoothing of rates to take into account general mortality trends. Taken together, these methods are referred to as *graduation*. The fourth part compares the two general graduation methods and discusses the advantages and disadvantages of each approach.

Definition of Mortality Rates

The mortality rate, for a given age (x), is defined as the probability that a life now aged (x) will die within 1 year. The actuarial convention is to denote this mortality rate as q_x [4, p. 53]. It can be theoretically calculated or practically estimated by taking the ratio of the number of people dying between ages (x) and ($x + 1$) in a year and dividing by the number of people who are alive at age (x) at the beginning of the year. Associated with the mortality rate is the

force of mortality, which is also called the *hazard rate* in reliability theory [4, p. 55]. This force of mortality, denoted as μ_x , can be interpreted as the instantaneous annualized death rate for a life aged x . The relationship between μ_x and q_x is

$$q_x = 1 - \exp\left(-\int_0^1 (\mu_{x+t}) dt\right) \quad (1)$$

The mortality rates, q_x , are generally broken down into various categories, such as gender and smoking status.

Another important variable in the mortality rate, which is pertinent in insurance investigations on standard lives, is the time since the particular life now aged x was insured, which is called the *duration*. When this variable is included in the mortality rate, the corresponding mortality rate is called the *select mortality rate* and is defined as follows:

$$q_{[x-t]+t} = \text{probability that a life now aged} \\ x \text{ who was insured} \\ t \text{ years ago will die within 1 year} \quad (2)$$

where x is the attained age and t is the duration. The age at issue would be $x - t$.

In general, the mortality rate will be an increasing function of attained age for fixed duration for ages above 30. For ages below 30, the mortality rates [5, p. 84] decrease sharply at the younger ages because of the infant mortality rate, remain fairly constant until the early teens, fall between ages 18 and 25 because of the accidental death rate, and then continue to increase to the end of the life table.

The mortality rate is an increasing function of duration for fixed attained age. The latter trend is true in the case of medically issued standard insurance when a life has to provide evidence of insurability by undergoing a medical examination. Hence a life now aged 35 who was insured 5 years ago at age 30 is subject to a higher mortality risk than a life now aged 35 who was just insured. This implies that

$$q_{[30]+5} \geq q_{[35]} \quad (3)$$

After a certain selection period, the effects of selection wear off and the increase in mortality as a function of duration becomes negligible. At that point,

$$q_{[x-t]+t} = q_x \quad (4)$$

For example, the 1975–1980 and the 1965–1970 basic tables assume a 15-year select period [1, 2]. In equation (4) the mortality rate q_x is called the *ultimate rate*. If a table of mortality rates does not include select rates, the mortality rate q_x is called the *combined rate*.

Estimation of Mortality Rates

The traditional method of estimation of mortality rates is to base the estimate on the usual binomial maximum-likelihood estimate, namely,

$$\hat{q} = \frac{X}{n} \quad (5)$$

where X is the number of annual deaths for that particular mortality class, n is the number of lives which are still alive in the beginning of the period for that particular mortality class, and $\hat{q}$ is the estimated mortality rate for that particular mortality class.

The data usually come in different groups by duration and issue age. For the construction of the 1965–1970 and the 1975–1980 basic tables, the data were in varying age groups by issue age (0, 1, 2–4, 5–9, and in 5-year classes up to 65–69, with 70 and over being the last class) and by duration (from 0 to 14).

Unfortunately, the number of lives that are still alive at the beginning of the period are not available, because insured lives are included in the study at all times. Consequently the binomial maximum-likelihood estimate does not apply. The traditional method is to interpret n in equation (5) as the number of exposures to death. For example, if an insured becomes part of the study halfway through a period, he will be counted as 0.5 of an exposure (see **Censoring**). These methods are discussed in [6–8]. An alternative method was developed by Kaplan and Meier, known as the *Kaplan Meier estimate* [9], which has been used to estimate survival probabilities in biostatistics applications (see **Hazard and Hazard Ratio**). The traditional actuarial method is equivalent to the Kaplan Meier estimate under certain assumptions [5, p. 323].

The result of this process will provide mortality rates for different classifications of issue ages and durations, but not for every integral attained age. To determine the select and ultimate rates by age and duration, as given by equations (2) and (4), the process of mortality rate graduation is required.

Graduation of Mortality Rates

Graduation is the process of taking the estimated mortality rates that are available in different age classes, and by a process of interpolation and smoothing, producing rates for all integral ages and durations. The purpose of interpolation is to provide estimates for $q_{[x-t]+t}$ and q_x for all integral ages from the grouped data estimates obtained from the insurance data. The purpose of smoothing is to take into account known mortality trends that may not apply to the estimates because of random fluctuations and differences among company experience that have contributed to the data.

There are two general methods for accomplishing this process. One method is to use smoothing techniques based on numerical methods. This area has a very rich history in the actuarial literature. Classical methods of graduation were discussed in Miller [10] and more recently by London [11]. One of the first known methods is the Whittaker–Henderson method [12, 13]. This method defines an objective function, which is a weighted average of the measure of fit (as measured by the sums of the squares of the differences between the smoothed mortality rates and the estimated mortality rates) and a measure of smoothness (as measured by third differences of the smoothed mortality rates). The Whittaker–Henderson method then selects the smoothed rates that minimize this objective function. This method was used to graduate the 1975–1980 basic tables [2]. More recent research on Whittaker–Henderson graduation methods by Lowrie [14] takes into account mixed differences and prior information. It also contains a very comprehensive bibliography of the development of Whittaker–Henderson graduation methods. A method of graduation based on kernel methods is discussed by Gavin *et al.* [15]. Bayesian graduation methods were discussed by Kimeldorf and Jones [16] and Hickman and Miller [17]. In this method, Bayesian ideas (see **Bayes’ Theorem and Updating of Belief**) were used to take into account prior information on the structure of the mortality curve, and this prior information was modified by using estimates based on data obtained from current mortality studies. This method was used in the construction of the 1965–1970 basic tables with the prior information based on the 1955–1960 basic tables [1]. Further research on this method has continued [18, 19].

More recent methods for interpolation and smoothing are based on the use of splines, which was developed by Schoenberg [20]. These methods have largely replaced the older methods because the solutions are based on linear systems of equations that could be easily solved on the computer, see [5, p. 485]. For an example involving cubic splines, see [5, pp. 485–514].

The other method of smoothing is based on using mathematical laws of mortality and fitting the data to these mathematical laws using regression least square methods or maximum-likelihood methods. This method was traditionally known as *graduation by mathematical formula*. Two such laws are those of Gompertz and Makeham, see [4, p. 78]. These laws relate the force of mortality to the attained age as follows:

$$\text{Gompertz Law: } \mu_x = Bc^x \quad (6)$$

$$\text{Makeham's Law: } \mu_x = A + Bc^x \quad (7)$$

Gompertz law assumes that the force of mortality increases at a constant rate per age. Makeham's law is a modification of Gompertz's law and is an attempt to take into account the smaller progression of mortality rates at the younger ages. Equation (1) can be used to express the mortality rates as a function of the Makeham and Gompertz parameters. Carriere [21] presented a great discussion and bibliography of the Gompertz law and other laws that have been proposed.

Several attempts have been made to modify these laws to model the selection effect. Tenenbein and Vanderhoof [22] developed several three- and four-parameter Gompertz curves to model the select and ultimate rates for attained ages above 30 and applied this method to fit the data upon which the 1965–1970 and 1975–1980 basic tables are based. Carriere [23] presented an 11-parameter model that applies for all attained ages and durations and used it to fit the data upon which the 1975–1980 basic tables are based.

Comparison of the Graduation Methods

The two methods of graduation are numerical methods and graduation based on mathematical formula. Each method has its advantages and disadvantages. The advantage of the numerical methods is that it will always form a set of smooth rates that provide a good

fit of the data. Considering the complexity of the mortality rates by age, this is a strong advantage. Its big disadvantage is that it cannot be used for extrapolation for ages that are not in the data set. For example, this method of graduation would be unreliable to estimate mortality rates at the higher ages [5, p. 488]. This is due to the fact that graduation by numerical methods is a purely mechanical method, which does not take into account any biological considerations.

Graduation by mathematical formula provides a method that will produce graduated mortality rates that are naturally smooth. The formulae are determined by taking into account the biological considerations. If the models work, then there is a greater justification for extrapolating beyond the ages in the data set. The main drawback is that it is difficult to produce a formula that works over the entire age range. For this latter reason, graduation by mathematical formula has not been widely used.

On the other hand, when it is desired to project mortality trends into the future, or to estimate mortality rates at the higher ages, or to estimate mortality patterns when data is not plentiful, mathematical models are very useful. Lee and Carter [24] and Lee [25] presented a mathematical model for forecasting mortality, and estimated the parameters using least-squares methods. The North American Actuarial Journal devoted almost an entire issue discussing the problem of forecasting mortality change and its impact on Social Security [26]. Wong-Fillipow and Haberman [27] adapted the Carriere model [23] to estimate mortality rates for lives over 80 by altering the parameters. Mathematical models for estimating mortality patterns at the higher ages are discussed by Buettner [28] and Watts *et al.* [29]. A logistic regression model was proposed for modeling pension plan mortality data by Vinsonhaler *et al.* [30].

Ethical Issues in Using Statistics, Statistical Methods, and Statistical Sources in Work Related to Homeland Security

This article addresses the role of ethics (*see Risk in Credit Granting and Lending Decisions; Credit Scoring; Syndromic Surveillance*) in work on statistics and homeland security (*see Managing Infrastructure Reliability, Safety, and Security; Game Theoretic Methods; Sampling and Inspection for Monitoring Threats to Homeland Security*), particularly focusing on issues relevant to the use of data mining (*see Change Point Analysis; Early Warning Systems (EWSs) for Predicting Financial Crisis; Privacy Protection in an Era of Data Mining and Record Keeping*) and risk assessment in counterterrorism applications. However, many of the principles and issues raised apply broadly to other statistical applications in the field related to homeland security and, indeed, to other applications as well.

Any consideration of ethical issues in any scientific or public policy context must begin with a clear understanding that ethics, science, and law while they often largely overlap and reinforce one another, sometimes diverge or even are in conflict. At the extreme, the law may be used to justify ethically flawed behavior or the perceived needs of science may be used to excuse serious ethical misconduct.

Historically, these conflicts have arisen most frequently in times of national crisis and so are particularly relevant to threat assessment generally and in the context of homeland security. In such pressing circumstances, the explicit consideration of ethical issues is often turned into a consideration of whether or not a given action is legal, or in conformity with permitted administrative arrangements, or simply in accord with the policies and priorities of the current government. In addition, because statisticians also properly perceive themselves as engaged in scientific work, they sometimes consider that the beneficence of their scientific work, particularly when apparently legal, excuses them from further ethical examination.

These practices and views, however, are short-sighted and in the extreme contrary to the laws

of many countries as well as international law (for example, national and international laws relating to genocide and crimes against humanity). It may be recalled that among the defenses offered by those charged with medical experiments, and the related collection of information and anthropological materials, in the so-called doctors' trial at Nuremberg after World War II were the defenses that (a) their actions were legal under current national law and (b) they were engaged in scientific work for an important and beneficent purpose. These defenses were explicitly rejected by the Nuremberg Tribunal when it found the defendants guilty of crimes against humanity. Subsequently, many national and international ethical statements, research policies and regulations, as well as related laws have adopted the same perspective.

In considering the use of statistics and statistical sources and methods in risk assessment related to the investigation of terrorism and homeland security, three different sets of ethical considerations arise: (a) those related to the validity of estimates made and conclusions drawn; (b) those arising when the data sources used were originally collected for statistical purposes under a pledge of statistical confidentiality; and (c) those related to the ethical character of the intermediary and final uses that the data, estimates, and analysis are intended to serve.

We take up each of these sets of issues in turn, referring to them as validity, statistical confidentiality, and responsibility, respectively, while recognizing that the terms validity, statistical confidentiality, and responsibility are incomplete descriptors of all the issues to which they refer. In doing so, we draw on the ethical standards adopted by the American Statistical Association (ASA) [1], the Association for Computing Machinery (ACM) [2], and the International Statistical Institute (ISI) [3], three diverse but relevant professional organizations.

Validity

Not only do statisticians and others using data have a scientific responsibility to use appropriate methods in data collection, analysis, estimation, and presentation, but they have an ethical responsibility to do so as well (*see Expert Judgment; Repeated Measures Analyses*). For example, a number of provisions of the ASA's Ethical Guidelines for Statistical Practice directly address issues of the validity of risk

assessments, particularly in the context of applications related to homeland security:

Guard against the possibility that a predisposition by investigators or data providers might predetermine the analytic result. Employ data selection or sampling methods and analytic approaches that are designed to assure valid analyses ... Assure that adequate statistical and subject-matter expertise are both applied to any planned study. If this criterion is not met initially, it is important to add the missing expertise before completing the study design ... Use only statistical methodologies suitable to the data and to obtaining valid results. For example, address the multiple potentially confounding factors in observational studies, and use due caution in drawing causal inferences ... The fact that a procedure is automated does not ensure its correctness or appropriateness; it is also necessary to understand the theory, the data, and the methods used in each statistical study. This goal is served best when a competent statistical practitioner is included early in the research design, preferably in the planning stage [1, Sections II.A.2, .4, .5, and .7].

And in reporting the results of any analysis or estimation process:

Report statistical and substantive assumptions made in the study ... Account for all data considered in a study and explain the sample(s) actually used. Report the sources and assessed adequacy of the data. Report the data cleaning and screening procedures used, including any imputation. Clearly and fully report the steps taken to guard validity. Address the suitability of the analytic methods and their inherent assumptions relative to the circumstances of the specific study. Identify the computer routines used to implement the analytic methods. Where appropriate, address potential confounding variables not included in the study ... Report the limits of statistical inference of the study and possible sources of error. For example, disclose any significant failure to follow through fully on an agreed sampling or analytic plan and explain any resulting adverse consequences [1, Sections II.C.2, .5, .6, .7, .8, .9, and .12].

While these principles seem only to be sound science, they have a heavy ethical importance as well, particularly in circumstances of risk assessment when the perceived threats are seen as so great that efforts are made to set aside sound scientific and technical cautions.

Confidentiality

Confidentiality issues play little role in ethical considerations for many kinds of risk assessment applications. However, in those applications that involve the use of data sets referring to human populations (for example, population censuses or population registration systems) or that involve efforts at individual or group surveillance of human populations, confidentiality (see **Public Health Surveillance**) issues may present important ethical as well as legal and policy challenges.

In order to promote as complete and accurate reporting as possible, both government and private agencies engaged in the collection of data for statistical purposes give assurances that the information provided will not be used to harm the data providers. A key element of this protection is the assurance that the information so obtained will be kept confidential (that is, not shared with other government agencies with intelligence, police, surveillance, and other non-statistical objectives) and only be used to generate statistics. The following are the words of the United Nation's Fundamental Principles of Official Statistics in this regard:

Individual data collected by statistical agencies for statistical compilation, whether they refer to natural or legal persons, are to be strictly confidential and used exclusively for statistical purposes [4, Principle 6].

Both the ISI's Declaration of Professional Ethics [3, Clause 4] and the ASA's Ethical Guidelines for Statistical Practice [1, Section II.D] underscore the principle of statistical confidentiality, which is embodied in the laws of many countries.

The ISI Declaration also places this principle in a useful context:

Statisticians should be aware of the intrusive potential of some of their work. They have no special entitlement to study all phenomena. The advancement of knowledge and the pursuit of information are not themselves sufficient justifications for overriding other social and cultural values [3, Clause 4.1].

Statisticians and others attempting to assess the impact of violations of statistical confidentiality often mistakenly focus their attention only on the technical indicator, "risk of disclosure", rather than also examining its ethically more-informed counterpart "the harm arising, given the disclosure". For example,

obtaining a list of persons aged 35–44 years from a confidential census file is generally less likely to generate grave harms than obtaining a list of persons from the same source showing specific ancestry, ethnicity, race, religion categories, etc.

It should be noted, however, that most laws protecting statistical confidentiality only safeguard against the misuse of microdata (that is, the individual record for each covered unit in the population). Other kinds of safeguards, including ethics, must be relied on to protect against the misuse of mesodata (that is, small area tabulations that may be used to target vulnerable population subgroups for human rights abuses) [5].

As a practical matter, there is often little to be gained by attempting to circumvent statistical confidentiality protections. Population data systems (for example, population censuses) used to gather data for statistics are usually very poor surveillance tools. The definitions and concepts used are often at variance with commonly understood meanings and the reporting errors common to any large-scale population data collection operation will give rise to many false positives and false negatives for any given population group of interest, seriously compromising the quality of any resulting risk assessments.

Responsibility

While some statisticians and other technical personnel involved in the work on risk assessment may at first consider that the ethical character of the intermediary and final uses of the data, estimates, and analysis on which they work are beyond their concern (see, for example, the discussion in Sigma Xi [6, pp. 52–54]), they should understand that legally and morally they are considered responsible for their actions under widely accepted current standards. This was the judgment of the Nuremberg Tribunal [7, p. 267] and is reflected in a number of relevant ethical norms. For example, Association for Computing Machinery's Code of Ethics and Professional Conduct begins with the following "moral imperative":

Contribute to society and human well-being. This principle ... affirms an obligation to protect fundamental human rights and to respect the diversity of all cultures ... Well-intended actions, including those that accomplish assigned duties, may lead to harm unexpectedly. In such an event the responsible

person or persons are obligated to undo or mitigate the negative consequences as much as possible [2, Sections 1.1 and 1.2].

The ASA's ethics guidelines are equally unambiguous:

Statistical tools and methods, like many other technologies, can be employed either for social good or for evil. The professionalism encouraged by these guidelines is predicated on their use in socially responsible pursuits by morally responsible societies, governments, and employers. Where the end purpose of a statistical application is itself morally reprehensible, statistical professionalism ceases to have ethical worth [1, Section 1.B].

Of course, decisions about the moral worth of a given application may require thoughtful discernment. However, the moral worth must be examined and not be simply assumed.

Promoting Ethical Work

Clearly a first, important step for sound statistically based work on risk assessment in the context of homeland security and counterterrorism (*see Counterterrorism; Sampling and Inspection for Monitoring Threats to Homeland Security*) (that is, work that is valid, ethical, and responsible) is the development of written statistical standards. Such standards are important not only in promoting sound work by having agreed-on protocols for reaching conclusions where quantitative data play a major role, but also by providing an opportunity for both statisticians and others to agree on such protocols independently from an actual crisis-laid situation and the tensions and emotions that decisions in such circumstances frequently evoke.

Such standards do not mean that mistakes will not be made either because the standards are ignored or that the standards adopted were defective in some essential respect. (For example, they were insufficiently specific or structured on incomplete or faulty assumptions). One way of improving the quality of such standards is to provide as wide a scrutiny of these standards as possible at various stages in their development. Despite their possible shortcomings, such agreed-on written standards provide some authority that quantitative analysts can cite in describing the basis for their conclusions in the face of those holding alternative views. It is also one way

of promoting the use of the best statistical methods in work on risk assessment.

Second, those engaged in risk assessment in any field, particularly those involved in work related to homeland security and counterterrorism, should routinely participate in ethical reviews of their work. To be effective, such reviews must also involve at least some persons with no intellectual, career, institutional, or personal stake in any specific outcome of the review. In this regard, many of the major past ethical failures have arisen in situations where none of those involved recognized that what they were doing posed an ethical problem (see, for example, [8, 9]). Accordingly, ethical reviews and discussions of ethics are one of the best preventive measures to take against serious ethical problems.

Evaluation of Risk Communication Efforts

Evaluation is a critical, yet often overlooked, component of any risk communication effort. Evaluation has been defined as a “purposeful effort to determine effectiveness” [1]. Without a systematic plan for evaluation, the communicator has no way of knowing if risk communication activities have reached the intended audience, have been communicated effectively, or have inspired behavior change or other actions.

Increasing interest in and application of risk communication in the last 25 years (*see Risk and the Media*) has been accompanied by the awareness of the importance of evaluating risk communication efforts [2–7]. Information and guidance has been provided on the use of evaluation in generalized risk communication program development [1, 3], message development [4], efficacy of different communication models for evaluation [8–10], assessment of agency effectiveness [11, 12], public participation programs and citizen advisory committees [13, 14], and community-based research [15]. This paper will look at the compelling reasons to conduct evaluation, the various types of evaluation, some established key factors in successful evaluation, and some of the barriers to conducting evaluation.

Why Evaluate?

The overall goal for conducting an evaluation is to improve communication activities. However, evaluation serves many purposes in risk communication efforts. Chelimsky [16] grouped different evaluation purposes into three general perspectives. Evaluation for *accountability* involves the measurement of results or efficiency, and usually involves the provision of information to decision makers to determine if the anticipated changes did or did not occur. Evaluation for *development* is done to improve institutional performance. Evaluation works both prospectively and retrospectively to help determine communication agendas, improve communication strategies, develop indicators of institutional effectiveness and responsiveness, audience response to the agency and programs, and whether resources are being expended

wisely. Finally, evaluation for *knowledge* is used to acquire a more profound understanding and explanation of communication processes and mechanisms. This type of evaluation contributes to the collective wisdom communicators may draw upon in continuously perfecting their craft.

Within these three perspectives, well-planned and effective evaluation of risk communication efforts serves many specific and valuable purposes:

To ensure the right problem is being addressed

Problem formulation is the most critical stage of any communication effort. However, like many problem-solving exercises, communication strategies frequently fail because of the following [17]:

- They are solving the wrong problem
For example, trying to develop a communication program to alleviate concerns about a potential health risk when the community is actually concerned about lack of control in decisions about the imposed risk or does not rate the problem as a priority.
- They are stating the question so that it cannot be answered
For example, trying to solve the question “How can we communicate this risk so that people will understand and accept our decision” is doomed to failure – communicating a predetermined decision, particularly in a controversial issue, will not ensure public acceptance, regardless of the communication strategy employed.
- They are solving a solution
As in the previous example, a one-way communication of an already determined risk-management solution does not address the risk problem – this can only be achieved through reciprocal communication and involvement of those potentially affected.
- They are stating questions too generically
For example, many agencies initiate a communication program with the general goal of improving communication, then cannot evaluate success because of the lack of clear, measurable, and relevant objectives.
- They are trying to get agreement on the answer before there is agreement on the question

For example, trying to obtain public consensus on options to reduce the risk from a new industrial facility, when the real question from the public's perspective is whether it should even be sited in that location.

Effective risk communication requires that all interested and affected parties be involved in the early stages of problem formulation and solution development for environmental risk problems [18, 19]. Periodic evaluation to check that the issues of concern to all parties are being addressed ensures that the process will be meaningful and resources will be expended appropriately.

To ensure the needs of all interested and affected parties are being met

Does the process have the "right participation", i.e., have those interested and affected parties who should be involved in the process been correctly identified? Has the target audience for the communication been correctly identified? Has the audience been correctly characterized? Evaluation is also important to ascertain if the process has the "participation right". Is the process responsive to the needs of the interested and affected parties? Have their information needs, viewpoints, and concerns been adequately represented? Have they been adequately consulted? If the participation is wrong and the needs of the audience are not being met, the communication program cannot be successful [18].

To ensure that the program objectives are being met

Objectives should be evaluated throughout the communication program to assess the following:

1. Are the objectives appropriate?
2. Will the plans meet the objectives?
3. Have the objectives been achieved?

To increase institutional understanding of and support for communication efforts

Communication, if conducted successfully and in an open and inclusive manner, should hopefully result in a productive means of addressing conflict and outrage. Unfortunately, many agencies do not readily recognize the value of programs that are "avoiding" the creation of problems. Evaluation provides the opportunity to impress upon senior managers the

value of well-planned and executed communication programs [1, 20].

To increase public understanding and support for communication efforts

Communication participants and audiences frequently fail to recognize the importance and relevance of the communication program until required to examine the process and outcomes.

To enhance and promote public participation in the risk process

Incorporating public participation into a process that is seen by many (public and risk managers alike) as being strictly based on scientific concerns is often problematic. Evaluation can serve to illustrate the value of participation to all skeptics.

To make optimum use of limited resources

Evaluation at the beginning and during the communication effort allows for programs to be modified before limited resources have been inappropriately expended.

To provide evidence of the need for additional funds or other resources

Evaluation is a valuable tool to assess the adequacy of resources (funds, personnel, and time) required to implement the communication program and keep it on track [1, 20].

To avoid making the same mistakes in future communication efforts

Evaluation ensures that continuous learning occurs throughout the process and that each subsequent program is improved accordingly [1].

Types of Evaluation

Evaluation should occur throughout the communication process. Three types of evaluation are generally recognized as being applicable to communication programs: formative evaluation, process evaluation, and outcome evaluation.

Formative Evaluation

Formative evaluation occurs early in the program, as objectives are selected, audience information needs

identified, and the communication strategy planned. Formative evaluation assesses the appropriateness of potential objectives, and the strengths and weaknesses of alternative communication strategies. Evaluation at this stage permits the necessary revisions and modifications to be made before program planning efforts are initiated.

Formative evaluation should determine if the problem analysis is sufficient, if the plans will meet the objectives, and if the plans will meet the audience needs [20]. Formative evaluations can also be used to pretest potential message materials for clarity, tone, and comprehensiveness [21]. While formative evaluation does not guarantee the success of a communication program, it does minimize the possibility that a program will fail owing to developmental flaws [22].

The type of formative evaluation used depends on whether it is conducted for problem analysis, audience assessment or communication strategy design. The scope of the communication program and available resources will also dictate the type of evaluation conducted. Formative evaluations can take the form of a simple pretest of materials, group “brainstorming” or discussions, surveys or focus groups, and personal interviews.

Process Evaluation

Process evaluation occurs during the implementation of the communication strategy, and is used to assess if the program is progressing as planned. Process evaluation can be used to modify the communication during implementation of the process, thus ensuring the resources are being effectively used. This type of evaluation is used to assess whether [22]

- activities are on track and on time;
- the target audience is being reached and understands the information;
- some strategies appear to be more successful than others;
- some aspects of the program need more attention, alteration or replacement;
- resource expenditures are acceptable and within budget; and
- if the budget was realistic to meet the stated problem and objectives.

The type of process evaluation employed will depend on the scope of the program and the available

resources. Process evaluation can range from routine record keeping of activities to a program checklist or even a management audit. Informal evaluation mechanisms, such as audience feedback or communicator observations, may also be useful in some cases. The most effective and efficient means of conducting a process evaluation is to make it a regular part of communication program planning and implementation. Process evaluation should be an ongoing activity in both new and established environment and health communication programs.

Outcome and Impact Evaluation

Also sometimes termed summative and/or impact evaluation, outcome evaluation occurs at the end of the program. It is used to assess to what extent the objectives were achieved, and the short- and/or long-term impacts of the communication program. The typical outcomes that are assessed in communication programs include changes in awareness, knowledge, behaviors, and beliefs and attitudes among target audiences [20]. Outcome evaluation is most effective when the program has clear and measurable goals and consistent implementation [1].

Outcome evaluation techniques can include focus groups, interviews, or questionnaires administered in person, by mail or by telephone [22]. Evaluation can also be done through activity assessments (e.g., demographics of callers to a hotline) or print media review (e.g., monitoring of content of articles appearing in the media) [1].

Impact evaluation is sometimes distinguished from other forms of outcome evaluation based on the scope and long-range timeframe of the impacts. This type of evaluation may be used to assess effectiveness of a program after a certain time period has elapsed. While an outcome evaluation can assess the audience’s perceived change in awareness or understanding immediately after the communication event, an impact evaluation can assess if that change was sustained over a period of time and affected practice or behavior. Impact evaluation can also assess the extent to which a program contributed to long-term, more global changes in health status. As these changes are the result of a multitude of factors, it is difficult to directly relate them to a specific program or activity. Information obtained from an impact evaluation may include such things as changes

in morbidity or mortality, or long-term maintenance of changed behavior [21].

Key Factors for Successful Evaluation

Evaluation cannot be “tacked on” to the end of a risk communication program. Effective and meaningful evaluations must be a carefully considered and planned component of risk communication activities. There are several key factors that should be considered in planning for evaluation [20, 23].

Organizational prioritization and commitment of resources

Decision makers within organizations must be committed to evaluation throughout the lifespan of a program (including conceptualization, implementation, and refinement). They must also be willing to commit the necessary staff time, budget, and other resources to evaluation as an integral part of the program. Evaluation cannot be meaningful unless appropriate resources are available to adequately plan and implement evaluation as an integral part of the communication effort.

Evaluation planning

Programs should be planned in advance of the communication program. Planning should draw upon multiple resources, including all interested and affected parties, conceptual theories, and literature reviews.

Specifying clear, measurable objectives

One of the most common mistakes in planning risk communication programs is failure to consider the specific outcomes to be achieved. If you do not know what you wanted to achieve how can you possibly decide if you have been effective? Program objectives should reflect the outcomes that will be measured during the outcome evaluation.

Measuring target audience characteristics at the outset to set the baseline for evaluating changes

Frequently, communication programs are designed to effect a change in audience awareness, knowledge, understanding, or behavior. However, it is impossible to assess if changes in knowledge or behavior have occurred if there is no baseline information on prior knowledge or behavior against which such comparisons can be made.

Developing clear plans specifying activities, audiences, staff involvement, budget, etc. to provide a basis for comparison

Process evaluations conducted during program implementation must also be compared against planned activities and intended resource allocations. However, these plans must remain flexible if process evaluation is to be effective.

Including appropriate data-gathering activities throughout the implementation of the program

This will ensure that the information necessary for evaluation is available when needed. Process and outcome evaluation are often limited by a lack of specific data required to conduct the evaluation.

Staff training and education

Communicators are not necessarily conversant in evaluation concepts or methodology. Training programs should be supplemented by specific discussions on planning, data analysis, interpretation, and dissemination for each specific program.

Reporting of evaluation research

Frequently, evaluation efforts are not reported, or are only reported in government reports or “grey literature” where they are not readily available as a means of learning from the experiences of others. In addition, program planners require simple and usable information from evaluations if these are to be successful in modifying ongoing programs or changing future efforts. The interpretation and presentation of evaluation efforts need to reflect this simplicity and direct approach.

Barriers to Risk Communication Evaluation

The factors that contribute to successful evaluation are also those that most frequently prove to be the most difficult obstacles. Internal organizational characteristics create the most common constraints to undertaking the tasks necessary for optimal evaluation. Management perceptions regarding the value of evaluation, and the level of support they subsequently provide for well-designed evaluation activities, are major barriers. Limited resources, such as funds and staff time, greatly restrict evaluation activities. Programs are also sometimes designed and implemented

under very restrictive timelines, thus precluding the necessary planning for evaluation.

Difficulties are often encountered in gathering the necessary information from the audience(s) on precommunication attributes and postcommunication assessment of changes. Audiences may be apathetic about evaluation efforts, or may try to please by providing the answers they think are desired. Evaluation efforts may also inadvertently become platforms for expressing dissatisfaction with other issues related to the risk or agency involved. In some jurisdictions, there may even be policies limiting the ability to gather information from the public.

External factors may create constraints to evaluation efforts. In communication programs with multiple partners, the logistics of evaluation are often difficult to coordinate successfully. There may also be difficulties in defining or establishing consensus between agencies regarding the objectives of the program [22].

The evaluation tools available to practitioners and their ability to employ those tools may limit evaluation implementation and effectiveness. Deciding on appropriate methodologies (such as a written questionnaire, individual interviews, or communicator observations) and then designing appropriate measures for that tool require that the communicator have both evaluation training and previous experience in diverse situations. It is also often difficult to separate the effects of program influences from other influences on the target audience in “real-world” situations [22].

Finally, despite best intentions, evaluation results are often not incorporated optimally into program planning and implementation. Some of the reasons suggested for lack of incorporation are as follows [23]:

- organizational inertia (organizations are slow to change);
- methodological weakness (poorly conducted studies have limited credibility);
- design irrelevance (evaluations conducted without input from program planners, decision makers, or the community); and
- lack of active or appropriate dissemination (evaluation results are either not distributed or not tailored to the needs of those in the program).

Summary

While it is acknowledged that evaluation plays a critical role for the communication components of all risk-management processes, it is not consistently applied in risk communication efforts. We need to learn more effectively from our efforts and apply these lessons to future communications, or we will be doomed to forever repeating the same mistakes.

Stakeholder Participation in Risk Management Decision Making

CYNTHIA G. JARDINE

Experience Feedback

Experience feedback (*see Reliability Data; Syndromic Surveillance; No Fault Found*) is the process by which information on the results of an activity is fed back to decision makers as new input to modify and improve subsequent activities. It plays a central role in the management systems for the prevention of accidents, incidents, and errors, since these events are symptoms of underlying weaknesses and indicate scope for improvements within the system where they occur [1].

Seen from this perspective, a risk assessment is a process by which knowledge gained from experience of historic industrial systems is transferred to a risk assessment team and used as a basis for recommendations on needs of risk-reducing measures in a system being analyzed (analysis object). The aim is to identify and mitigate possible future accidents in order to reduce the risk to an acceptable level. The object of the analysis may be an existing industrial system, a new system, or a system being modified. The necessary transfer of knowledge is accomplished through different channels, (Figure 1) [2].

Explicit and Tacit Knowledge

Figure 1 distinguishes between explicit and tacit knowledge, and both are experience based [3]. Explicit knowledge is rational and can be expressed in text, numbers, and formulas. It includes theoretical approaches, problem-solving heuristics, manuals, and databases. Tacit knowledge, on the other hand, is personal, subjective, and context related and is not directly suited for documentation. It includes value systems, images, intuition, and mental models and know-how. Some channels are dominated by the transfer of explicit knowledge, and here records of accident and error data play an important role. Other channels involve participation by personnel at the sharp end in the risk assessment team. This makes it possible to tap their tacit knowledge gained through day-to-day experiences with incidents and errors.

Experience Databases and Experience Carriers

Experience databases are representations of explicit knowledge and play an important role in quantitative

risk assessments. They are used in the identification of hazards and in the modeling and estimations of frequency and consequences of unwanted events (Figure 2). Examples of experience databases are as under:

- incidents and accidents databases with data from investigation reports of relevant systems;
- reliability databases with failure data for hardware and software for relevant systems;
- human reliability databases with data on human errors in different types of tasks;
- exposure databases with data on the extent of the operations for which accident, incident, and failure data is collected (e.g., number of hours of operation, number of times an activity has been carried out);
- data on escalation probabilities, e.g., likelihood of ignition after gas leakage;
- site specific population density statistics for the surroundings of the analysis object in question;
- site specific meteorology data.

Experience carriers represent explicit knowledge at a higher level of synthesis than experience databases. Here experience from operations and accidents on historic industrial systems and from earlier risk assessments have been summarized and codified into standardized work processes, decision criteria, analytic models etc. in a way that makes sense to the risk analyst. Examples of experience carriers directly used in risk assessments are as follows (Figure 2):

- *Regulatory requirements to risk assessments*

Examples of these are the provisions in the EU Directive on the control of major-accident hazards (Seveso Directive), the US OSHA Standard 1910.119 on the process safety management of highly hazardous chemicals, and the UK Offshore Installations (Safety Case) Regulations [4–6]. Work on the EU Directive was initiated after a major chemical accident in Seveso, Italy in 1976. The recommendations in Lord Cullen's investigation report on the Piper Alpha disaster in the North Sea in 1988 were followed-up in the UK Safety Case Regulations [7].

- *Standards and handbooks on principles and practice in risk assessments*

They include knowledge of relevance to the risk analyst community such as analytic models, computer

Figure 1 Channels for transfer of experienced-based knowledge in risk assessments

codes for simulation, risk assessment methods, and experience checklists. One example is the Norsok standard Z-013 on risk and emergency preparedness

analysis used by the Norwegian offshore industry [8]. Another example is the IEC standard 61508 on functional safety of electrical/electronic/programmable electronic safety-related systems, used to specify requirements to safety instrument systems using a risk-based approach [9]. These standards are typically developed by expert panels with extensive risk assessment experience. They give detailed accounts on how to execute risk assessments.

- *Decision criteria regarding highest tolerable risk*

A risk level above this limit will trigger requirements to implement risk-reducing measures. The limit is usually based on statistics from historical systems on frequencies and consequences of accidents. Such statistics gives indications of risk levels that have been possible to accomplish in the past and stakeholders' tolerance to accidental losses. Similarly, there are decision criteria on the lowest risk level that is reasonably practicable, below which further risk reduction is deemed unnecessary.

- *Phenomenological knowledge about accident scenarios, failure mechanisms, human tolerance limits, performance barriers*

This type of knowledge is typically documented in scientific and professional articles, textbooks, and

Figure 2 Use of explicit knowledge in risk assessments

handbooks. Since major accidents are rare events, experience data from in-depth accident investigations on the latter part of the accident scenario determining the extent of the consequences and efficiency of barriers is often insufficient. Knowledge, here, is more often based on laboratory and field experiments and simulations of physical processes and on expert judgment.

In the follow-up of the risk assessments, experience carriers documenting risk-reducing measures such as regulations, standards, and guidelines are used to reduce the risk to a tolerable level.

Update with New Experience

For the risk assessment results to be valid, the experience basis needs to be kept updated. The generic incident and failure rates used in risk assessments are based on statistics from the operation of industrial systems in the past [10]. By aggregating data from systems with similar characteristics to the analysis object, a generic average for this type of system is achieved. The question arises on how representative this generic average is for the new industrial system under study with respect to state of the art in technology, operations, and maintenance and relevant accident risks. The historic incident and failure experience has already been used to develop preventive measures, and some of the accident risks represented in the data may not be valid for the analysis object. There is a trade-off between the needs

of representative data on the one hand, and sufficient data with respect to statistical uncertainty on the other. Since accidents are rare events, this trade-off is especially critical for accident frequencies. Trend analysis and expert judgment are sometimes used to establish new frequency estimates to compensate for the inadequacies in experience update.

Updates of regulations and standards often involve bureaucratic and long-lasting procedures. Companies may prefer to develop their own experience-based best practice as a supplement to these documents [11]. The feedback loop here is usually shorter and less delayed than is possible in the update of regulations and standards.

Nonaka's theory of organizational knowledge creation may be used to illustrate how the company's risk analyst community interacts to develop such best practice [12]. The risk analyst's individual knowledge is experience based and acquired through participation in projects where risk assessments are conducted (Figure 3). For a best practice to develop, the individual and mainly tacit knowledge needs to be communicated and discussed within a community of colleagues. This discussion results in the development of shared knowledge that is made explicit and documented. This new knowledge has to be justified to become best practice. This is a management task and takes place in the functional organization. Here the proposed best practice is judged in terms of efficiency and effectiveness and compliance with the legal environment and industry standard. The new best practice is then implemented in the functional

organization's knowledge base for use in future risk assessments.

Risk Assessment as an Arena for Experience Exchange

Similar experience exchange and learning processes take place within the risk assessment team. Dependent on the scope and aim of the risk assessment, the team needs to include internal stakeholders with an adequate variety of knowledge and values to promote validity and reliability of results, learning among team members, and acceptance of decisions made by the team. The assessment team could, for example, be made up of systems designers, risk analysts, and personnel at the sharp end with operational experience from similar systems. Operational experience is especially important in judging the relevance of assumptions in the risk assessment and in modeling the early part of the accident sequence, where production disturbances and human and technical errors play an important role. Biases and misconceptions may be avoided, if the group members challenge propositions and discuss alternative interpretations.

Documentation of the Experience Basis

Risk assessments are decision support tools used in judgments of needs of risk-reducing measures. For the decision makers to trust the validity and reliability of the results, the documentation of the assessment needs to be comprehensive, well structured, and transparent [13]. It is thus necessary to document the sources of the experience input to the analysis and their relevance. This includes the databases on accidents and failures that have been used and the experience represented in the analysis team.

Example: Experience Feedback in Environmental Risk Assessment

The oil companies on the Norwegian Continental Shelf carry out environmental risk assessments as part of the permitting process for drilling operations. They apply the results to verify that the acceptance criteria for environmental risk owing to oil spills are met, and to select and dimension safety and emergency preparedness measures. A community of

practice made up of environmental, drilling, and risk assessment experts from Oil Companies and Consultants has cooperated in developing guidelines for the environmental risk assessments [14]. The work on this experience carrier started as a result of new safety legislation in the beginning of the 1990s. It has evolved through different revisions based on experience from previous risk assessments, and represents the recognized best practice of oil spill risk assessment in the Norwegian oil industry. The guidelines standardize input data, models, analysis methods, and risk acceptance criteria, and make it possible to compare results between companies.

When work on environmental risk assessments started, there was a general lack of phenomenological data, e.g., on the distribution of sea birds in open sea. The first generation of data and models used in the risk assessments had a low fidelity compared to the observed variations in distributions in time and space. Improved databases and new simulation models, developed through an interaction between research and risk assessment practice, now map these variations with sufficient fidelity.

Another example of the results of the knowledge-creation process is the development of so-called key parameters for environmental damage. In the absence of species-specific data, the community of practice, has decided to develop and use standardized key parameters for the expected restitution time for a population of sea birds or mammals following a reduction in the population due to acute discharge of oil to sea. An acute discharge resulting in a reduction of the population by up to 5%, for example, is expected to give a restitution time of less than 1 year in 50% of the events and 1–3 years in the remaining events.

Blowout data is required to carry out environmental risk assessments of offshore drilling operations. To meet this need, SINTEF, in Trondheim, has established an Offshore Blowout Database [15]. Input data on blowout incidents and exposure (number of drilled wells, etc.) are derived from public sources such as the US Mineral Management Service, the Health and Safety Executive in the United Kingdom, and the Petroleum Safety Authority in Norway. Complementary information on blowout incidents has been secured, where possible, through direct contacts with the Oil Companies or drilling Contractors in question. The next step has been to develop recommended

blowout frequencies as basis value in risk assessments of well operations of North Sea standard [16]. The recommended frequencies are updated regularly on the basis of new experience. The following measures have been introduced to ensure a sufficiently large database for frequency estimates, while, at the same time, ensuring that the recommended frequencies are representative to North Sea operations:

- The data used for the frequency estimates are limited to the North Sea, the US Gulf of Mexico, and the Canadian East Continental shelf, where drilling operations are carried out according to a similar safety standard.
- “Irrelevant data”, i.e., incidents that are not relevant with respect to equipment, requirements, or practices in the North Sea, are omitted.
- Weighted averages for the last 20 years are used, where newer data are given a higher weight in the calculations of frequencies.

URBAN KJELLÉN

Expert Elicitation for Risk Assessment

Risk assessment inherently involves estimation of subjective factors. While consequences of a particular hazard event may be reasonably well understood or predictable through physical models, the frequency of an event is often much harder to assess. The prevalence in the daily paper of “100-year floods”, surprise events, and unexpected system failures point out a fundamental limit of risk knowledge [1]. Even when risk frequency can be estimated by observations over time, these observations often cannot resolve fundamental uncertainty over whether that observed frequency is either stable, or could change in the future.

Expert opinion (see **Risk in Credit Granting and Lending Decisions; Credit Scoring; Operational Risk Modeling; Sampling and Inspection for Monitoring Threats to Homeland Security**) gathered in one guise or another, is often the only reasonable source of information available by which an estimate of future event frequencies can be made [2–4]. *Expert elicitation* (see **Bayesian Statistics in Quantitative Risk Assessment; Expert Judgment; Uncertainty Analysis and Dependence Modeling**) is the term for a set of methods and practices that have developed within the social sciences and statistics to gather risk information from subjective expert information in a way that (as much as possible, though never absolutely) minimizes common sources of bias and ambiguity [5].

Expert elicitation is a qualitative practice, rather than a discipline or tool. A variety of techniques exist, some of which have been evaluated under controlled tests. By and large, however, the results of such tests have revealed a number of basic caveats and biases in the ability of subjects (expert or not) to assess risk, rather than providing “the right way” to gather expert opinions.

At its heart, all attempts at expert elicitation reduce to a structured questioning strategy. Elicitation of expert opinion is most often conducted *via* face-to-face interviews with *subject matter experts*. However, a wide range of alternative elicitation strategies are also common, including group exercises, use of survey instruments, simulations and role playing, and direct observation of expert choice.

The development of a particular elicitation strategy, often in the form of a set of questions or protocol, called an *elicitation instrument*, requires a detailed understanding both of the risk subject matter and the capabilities, needs, and communication styles of the subject matter experts. Before embarking upon an effort to gather expert opinions on a particular risk, it is vital that, at a minimum, the following factors are taken into account:

- Is the elicitation instrument ethical? Is information being gathered in a way that protects the welfare of the expert subjects? In particular, while gathering information on medical risks, it may be necessary to submit the elicitation instrument for a human subjects committee review.
- What cultural, social issues may cause elicitation subjects to misunderstand, or misanswer the questions being asked?
- Is the elicitation instrument being applied to the right community of experts? How well do the questions probe issues about which the experts have knowledge and the ability to effectively assess the meaning of the risks being examined?
- Has the elicitation instrument, and the way questions are formulated, been crafted such that they obtain risk estimates that are as free from bias and ambiguity as possible?

Deciding upon the application of a specific expert elicitation strategy is highly driven by situational factors, rather than the application of a rule-set or “cook-book”. What follows, therefore is an attempt to distill from the literature, a set of models for different risk expert elicitation scenarios, along with an introduction to the various uses of risk elicitation that have been reported in the literature.

Models of Expert Elicitation of Risk

There are different kinds of risks and sources of risk. Approaches to expert elicitation of risks vary in the literature depending upon which of these different kinds of risks are being considered. Understanding which kind of risk, and the underlying type of mechanism behind it, are essential in creating an effective, suitable elicitation instrument. On the basis of the underlying mental or knowledge model being used to describe a risk, very different kinds of elicitation strategies may be employed, and the ability of

subject matter experts to provide useful *contributory expertise* would vary [6]. From the standpoint of developing an elicitation strategy, four different categories of risk origination need to be distinguished from one another: basic events, system processes, competitive games, and social negotiation.

Basic Events

The vast majority of expert elicitation case studies focus on risks that are to be characterized using a single probability distribution, or frequency estimate. From an elicitation standpoint, experts grappling with a basic event risk estimation problem are modeling risk as being generated by a single (though possibly internally complex) black-box process. Expert elicitation is used as a “second best” source in lieu of being able to observe the process long enough to obtain direct measurements for the characteristics of the unknown black-box function (central tendency, variance, etc.).

The goal of this type of expert risk elicitation is to discover a “best available estimate” for this potential distribution on the basis of the pattern of outcomes that have been observed so far, and obtain judgments from one or more experts for the characteristics of the actual black-box outcome distribution [7].

Expert elicitation of basic event modeled risks focus on gathering quantitative values. For example, an elicitation session could focus on trying to describe the probability of a jet engine turbine blade failure in terms of the most likely number that might occur over a particular period of time, as well as the least and most number of failures that are likely to be observed. From this information, a basic sense for an underlying distribution of turbine blade failure events can be constructed from the expert estimates. This distribution, however crude it may be, can then be described using a probability distribution function, or fuzzy set (*see Environmental Remediation; Dependent Insurance Risks; Early Warning Systems (EWSs) for Predicting Financial Crisis; Near-Miss Management: A Participative Approach to Improving System Reliability*), and used as part of any number of different risk analysis methods (fault tree (*see Systems Reliability; Imprecise Reliability; Fault Detection and Diagnosis*), simulation (*see Asset–Liability Management for Life Insurers; Equity-Linked Life Insurance;*

Markov Modeling in Reliability; Reliability Optimization), etc.).

Examples of such uses of expert risk elicitation include analyses from virtually every field of risk study; everything from nuclear power plant safety studies [8], to managing the risks of organ donation IT systems [9], to Search and Rescue resource allocation [10], to real estate markets [11], to climate change modeling [12].

In part, because of the prevalence of “basic event risks” in the expert elicitation literature, and in part, because this type of model for risk is the most verifiable *via* controlled experiments against observed risk data, a good deal is known about how and under what circumstances experts do, and do not, perform well [13, 14]. In broad-brush strokes, systemic errors in expert perceptions of risk can be divided among two main sources of biases: *cognitive biases* and *motivational biases* (*see Expert Judgment*).

Cognitive biases, the most rigorously studied category of bias from the standpoint of behavioral science experimentation, covers a host of different mechanisms. All of these mechanisms stem from basic cognitive and mental traits that seem to be part of the inherent limits on human risk reasoning. When constructing elicitation instruments, it is important to approach these biases with a degree of humility – for a variety of evolutionary reasons these biases seem to be a deeply embedded set mental behaviors for all people, and a questioner simply cannot ever be completely certain that the results are as unbiased as one hopes.

Availability bias reflects the observed tendency of unusual or memorable events to skew risk estimates in comparison to more mundane (but often far more prevalent) events. Availability bias is commonly seen in surveys of risk perceptions of air traffic safety following a well-publicized aviation accident [15, 16]. *Anchoring bias* is the tendency to latch onto an initial belief of the magnitude of a risk estimate, and insufficiently adjust this initial mental risk estimate as new information becomes available. Anchoring bias has been demonstrated in a number of controlled studies in which experts were presented with an initial arbitrary number prior to being asked to judge a specific risk [17]. In the real world, the classic strategy of letting the “rube” win the first couple games of roulette, demonstrates, in part, how anchoring bias can be manipulated. *Inconsistencies in probabilistic*

logic also are a common source of cognitive biases in risk elicitation [18]. These logic inconsistencies stem from a variety of memory, logic, and reasoning failures that all subjects (expert or not) seem to share. Common examples of inconsistencies in probabilistic logic include failing to remember that the sum of all probabilities assigned to the outcomes of a risk must sum to 1, or failing to assign a lower probability to the union of a set of independent events, than to any single member of that set.

In addition to biases caused by expert cognitive limitations, expert opinion may be biased by motivational effects – such as relationships, employment, and past experiences. Motivational biases can also unwittingly be introduced by the elicitation instrument *via interviewer bias*. Just as subject matter experts may have a tendency to misestimate risk frequencies on the basis of preconceptions and cognitive limits, so too may bias be introduced during interpretation based on what results the elicitation administrator thinks “make sense”, or from the administrator’s belief in a prior risk hypothesis. Likewise, there is the possibility that the elicitation instrument itself may be structured in a way that unintentionally causes bias. Even if the elicitation instrument is free of any bias held by the administrator, it may still be flawed, unclear, or structured in a way that will lead to unintended (and always very unwanted from the standpoint of the poor researcher) patterns in risk estimate results [19].

The most important mitigation strategy for all types of bias is to carefully craft, administer, and test the elicitation instrument. Whenever possible, the elicitation instrument should be edited by other researchers familiar with the kinds of bias common to expert risk elicitation/general survey analysis, and holders of subject matter contributory expertise who will *not* participate in the final elicitation. Common strategies to minimize bias include the following:

- ensuring that risk elicitation questions are nondirective, do not suggest quantitative anchor points either in the question or in any examples on how to answer the question, and do not ask responders to estimate one risk in relation to a risk estimated in a previous question;
- use of group risk elicitation exercises (*see Group Decision*) such as the Delphi method to control

against any single source of preconception, limitations on any single expert’s ability to imagine a risk scenario;

- use of structured probability distribution methods, such as providing Sherman Kent scales, the Stanford probability wheel, use of odd ratios to describe particularly small probability events, employment of interval elicitation, and other methods to help ensure risk concepts, values are clearly and consistently displayed;
- employment of logic and probabilistic reasoning aids such as analytical hierarchy process reasoning methods [20];
- frequent reminders during the administration of the elicitation instrument of definitions, what terms mean, and how risks are described;
- ensuring that the elicitation instrument meets the time constraints for the elicitation, and that risk experts will not be overly tired, bored, or annoyed by the end of the session.

System Process

Elicitation of expert opinion for risks generated by system processes requires a set of approaches somewhat different from those employed for basic event risks. Risks emerging from single events are assumed to be *independent*, allowing the subrisks contributing to an overall frequency estimate to be elicited separately and later combined together as part of a fault tree or similar quantitative structure such as a Monte Carlo simulation.

Risks modeled as being part of system processes require that the elicitation focus on the problem of gathering estimates for joint, *correlated*, risk distributions. These risks are generated by the complex interactions between individual risk generating processes—the term *system process* is used because underlying the creation of an overall risk is an underlying dependency structure that while perhaps only partially understood, is composed of correlated subprocesses.

Consider the problem of estimating the risk that a city levee system will fail over the next period of time. Suppose little or no data exists from which to estimate this risk as a single distribution obtained from observation (since we can’t flood a city on a whim), or from the experience of analog city levee system failures. Instead, such data as does exist in the form of storm prevalence, the relationship between

maintenance practices, levee upkeep and patterns of maintenance disruption by bad weather, and on a host of other subsystem activities (perhaps the relationship between storm patterns and political allocation of levee maintenance resources) required to keep the levee system functional against a subpopulation of storms that might be encountered. To estimate the risk of the levee system failing during a storm, these disparate data series can be stitched together to create an overall risk from the interwoven *system* of correlated processes contributing to overall failure frequency [21].

From an elicitation standpoint, two interesting difficulties exist. The first is that, as in the case of many engineered systems, no single expert will have the span of necessary contributory expertise to characterize the risk system as a whole. This implies that much of the challenge of the expert elicitation is to develop a common representation for the risk dependency structure. The second challenge of eliciting system process risks is that ultimately there may never be sufficient system level data to validate the overall risk model. Development of a reasonable elicitation derived estimate for the risk depends on reconciling different, possibly conflicting expert opinions.

Elicitation of a common representation for the risk process depends upon understanding what is known about the individual processes that relate to risk generation. For example, in the case of the levee example above, there is some relationship between maintenance on the levee and the likelihood that it would fail during a particular storm. If the set of, and relationships between, contributing risk processes are fairly simple, it may be possible to sketch and annotate a representation of the important dependencies between risk processes on a piece of paper over the course of a couple of expert elicitation sessions.

If the interactions between risk processes are more complex, elicitation sessions may be required with many different experts, each of whom may only be familiar with a very small set of the overall risk processes contributing to the overall risk estimate. In these cases, a more formalized process may be required to help ensure that the elicitation instruments, and results, are administered evenly across the spectrum of experts. More formalized risk modeling structures, such as Bayesian networks, may be constructed, during the elicitation

exercise to help negotiate a common risk descriptive representation [22].

The elicitation of system process risks is much less well studied than that of basic event models for risk [23]. Far less is known about the kinds of bias that occur when experts are asked to develop a system structure model. The use of a common *ontology* of concepts involved in the system process risk is a useful way to prevent confusion over what risk processes exist, and how they relate to each other. The use of software supporting representation of how these risk processes interrelate *via* the use of network graphs can also be valuable. Expert group development of a simulation model for the risk process is another way that has been explored to capture complex system interrelationships more accurately.

Elicitation of system process risks is a relatively new approach to risk estimation. It has been made useful largely by the spread of Markov chain Monte Carlo (*see Enterprise Risk Management (ERM); Global Warming; Reliability Demonstration; Bayesian Statistics in Quantitative Risk Assessment; Geographic Disease Risk*) approaches to joint distribution estimation [24]. Unlike the elicitation of basic event modeled risks, system process risk elicitation does not have a robust body of quantitative, behavioral science inspired experiments from which to characterize cognitive biases and inform “best practice” elicitation methods [25–27]. Many of the elicitation techniques applicable to basic event risk elicitation are applicable and can be used. Ensuring that as many different relevant sources of contributory expertise are included in the process to develop, review, and revise the risk process representation is as good advice as can be offered, given the state of research into this type of expert elicitation.

Competitive Game

Competitive game risks (*see Managing Infrastructure Reliability, Safety, and Security; Risk Measures and Economic Capital for (Re)insurers; Mathematics of Risk and Reliability: A Select History; Game Theoretic Methods*) arise from the interaction between two nonprobabilistic actors, acting in opposition to one another. Determining the risk of a terrorist or criminal action of a particular kind is a prevalent example of a competitive game

risk elicitation problem. Eliciting risks resulting from competitive game processes as a basic event risk is an analytic mistake. It is, unfortunately, from a policy-making standpoint, also a prevalent one. A basic understanding of *game theory* is desirable to develop an effective elicitation instrument for these types of risks.

Risk from competitive game processes do not arise from natural processes, but from hazards being *actively generated by another actor* with competing objectives. For example, in the case of screening for firearms at the airport, the distribution of attempts to slip a gun through a detector are not created by a “state-of-nature” black-box process. Rather, this type of criminal action is the result of a set of interactions between the strength of detection defenses and the cost–benefit calculation of those who want to hijack an aircraft. From the standpoint of frequency estimation, the distribution of this risk is due to uncertainties over the costs, benefits, motivations, and abilities of each side in this repeated period strategy transaction.

Expert elicitation of risks from competitive game processes should *not be performed as though these risks stem from basic event processes* [28]. In general, it can be expected that assessment of a particular risk will greatly depend on the following:

- how well experts understand the strategy, information available, and cost–benefit calculations of each side;
- the nature of the game between both sides – is it a single transaction or a multiperiod game, for example;
- the ability to elicit information from the different parties to the competitive game process.

The biggest single difficulty for this type of expert risk elicitation is finding sources of contributory expertise for both sides of the competition. Typically, criminal and terrorist networks do not respond to elicitation requests. To get this risk information, a common strategy is to establish red teams, or employ role-playing exercises that (as much as possible) force experts to immerse themselves in the decision-making context of the other side [29]. Such elicitation exercises can greatly vary in formality from counterthinking scenarios, to table-top exercises, to the formation of “red teams”, or even computer assisted war-gaming type exercises.

Whichever type of elicitation strategy is employed, typically the result is a ranked list of preferred strategies for each side to the competition, given the strategy chosen by the other side. One strategy to convert these ranked preferences into a scenario response distribution is to normalize across ranking or utility scores, to produce a rough distribution describing scenario responses.

Social Negotiation

Social negotiation situations are the most subjective risk process for expert elicitation. Social negotiation risk elicitation exercises differ from elicitation of other risks in that the actual risk quantification is not the purpose of the exercise. Instead, through the language of risk, elicitation is used as a means for negotiation and compromise over disagreements involving social justice, allocation of resources, and distribution of social costs and benefits.

Social negotiation models for risk are commonly encountered in the context of facility site determination, not in my backyard (NIMBY), and similar social-technical disputes. Very often all parties to the elicitation will enter the exercise with their own risk estimates. Whether these are based on “the best available science” or not, these estimates are an amalgamation of communal needs and fears [30]. The purpose of the elicitation is not inherently to convince one side or the other their risk beliefs are wrong, that, for example, the risk of living next to a nuclear power plant is equivalent to “eating 40 tablespoons of peanut butter” [31]. Rather, regardless of what the “actual” risk level is, the purpose of the elicitation is to see whether a resolution can be reached to a political dispute *via* the language of risk estimation [32].

As an inherently political process, elicitation of expert opinion in this context implies a broad definition of contributory expertise to include almost anyone identifiable as a stakeholder in the hazard as “an expert”. Development of an elicitation instrument may also rely more on communal processes to develop fair and open procedures. Meetings, town-hall sessions, and “open microphones” are more likely to be used as the elicitation mechanism rather than structured interviews or survey instruments.

The main success metric for elicitation of risk stemming from social negotiations is the creation of a fair process for information gathering. As formal

quantification of expert opinion is unlikely to be needed beyond development of a clear consensus for the odds of the hazard, the issue of bias is inherently secondary to whether both sides can live with the compromise. As an exercise in political decision making, the design of the elicitation instrument will be highly situational depending on customs and the nature of the risk dispute.

Uses of Expert Elicitation of Risks

Basic event, system process, and competitive game risk elicitation exercises are generally conducted so that qualitative information can be converted into quantitative results. Up through the 1980s, results gathered from expert elicitation were primarily used to populate the nodes on fault or event trees. Expert elicitation served as a supplementary technique to fill areas on a fault tree that could not be estimated using observed data. The focus of elicitation centered on central tendency or odds estimation, especially for large technical systems.

With improvements in microcomputers, gathering the shape of basic event risk distributions became more prevalent. Software tools like Analytica, Crystal-Ball, and other Monte Carlo sampling tools allowed users to quickly and cheaply analyze both the central tendency and spread of a risk distribution resulting from combinations of basic events. To populate these risk models, however, it was necessary to gather, at a minimum, the basic family of distributions described by the expert's risk understanding. Such risk elicitation methods provided data that became incorporated into a wide variety of complex risk simulations.

Bayesian methods (*see Reliability Demonstration; Bayesian Statistics in Quantitative Risk Assessment; Clinical Dose-Response Assessment*) for risk estimation have always provided a natural justification for use of expert elicitation. The use of expert opinion to provide an informative prior is at the heart of Bayesian reasoning. Mathematically, however, the joint integration required to effectively combine the expert derived prior with the data derived posterior, was often intractable [33]. With the development of practical tools implementing the Metropolis-Hasting algorithm and other Bayesian estimation methods, the use of expert risk elicitation has become more important than a technique

to supplement a lack of directly observed data [34]. As expert elicitation of risk is increasingly used by Bayesian statistical practitioners, a better understanding of how techniques to gather system process risks (in the form of Markov chain Monte Carlo) are likely to emerge over the next decade.

Expert Judgment

Judgment involves the weighing of available evidence and reaching a balanced conclusion from that evidence. We bring in experts to provide these judgments because they have developed the mental tools needed to make sound evaluations. These mental tools include knowledge of what evidence can be brought to bear on the question, the abilities to weigh the validity of various pieces of evidence and to interpret the relative importance of various facts or assertions, and to craft a view from an ensemble of information that may be inherently limited or self-conflicted. In risk analysis these judgments nearly always entail uncertainty so that the judgments are not definitive but reflect what we know and what we know we do not know.

The natural language of uncertainty is probability. It provides a precise way to encode knowledge that is inherently imprecise. It puts judgments in a form where they can be manipulated mathematically, and thereby be integrated with other pieces of information and used in models to assess risks. These judgments are essential in many analyses of risk. For example, see [1–5].

When we set about acquiring expert judgments for an analysis, there are a number of decisions that must be made about how to proceed. These include the following:

- selecting the issues to be addressed by the experts
- selecting the experts
- organizing the effort
- choosing a method for combining multiple judgments, if needed.

Posing Questions to the Experts

The first stage of developing an expert judgment process is to determine the objectives and desired products. Judgments can be made about a number of different things. Some judgments are about facts, while others are about values. Roughly speaking, a fact is something that can be verified unambiguously, while a value is a measure of the desirability of something.

For example, you might believe that it is better to expend tax dollars to fight HIV abroad than it is to improve the educational level of impoverished

students at home. This is a value judgment. You might even be able to express in quantitative terms your affinity for one use of tax dollars *versus* another. But another person may hold very different views and neither of you can be said to unequivocally correct. It is a matter of preference, not of fact. In contrast, you and another person may hold different views about the rate of HIV infection. In principle, it is possible to determine this rate (through medical testing and statistical analysis) and thus the judgments are about a fact. This article is limited to judgments about facts, while the discussions in the articles on Utility Functions and Preference Functions focus on values.

Judgments about facts can be further classified. Focusing on judgments often made in risk analysis, we find that judgments can be made about

- the occurrence of future events
- the values of parameters
- the appropriateness of competing models in their ability to reflect reality.

Not all questions, however, are of equal consequence in quantifying risk. There will normally be a few major questions that drive the uncertainty about the risk. These questions are candidates for a more structured expert judgment activity. Other issues – those that play a minor role – can often be treated less formally or through sensitivity analysis, saving the resources for the more important issues. A sensitivity analysis using initial estimates of probabilities and probability distributions is often performed after an initial risk model has been structured. The sensitivity analysis identifies those questions deserving of a more penetrating study.

However, not all issues lend themselves to quantification through expert judgment. In addition to being important contributors to uncertainty and risk, an issue that is a candidate for expert judgment analysis should satisfy the following conditions:

- It should be resolvable in that given sufficient time and/or resources, one could conceivably learn whether the event has occurred or learn the value of the quantity in question. Hence, the issue concerns a fact or set of facts.
- It should have a basis upon which judgments can be made and can be justified.

The requirement of resolvability means that the event or quantity is knowable and physically

measurable. We consider a counterexample. In a study of risk from a radioactive plume following a power plant failure, a simple Gaussian dispersion model of the form $y = ax^b$ was employed [1]. In this model, a and b are simply parameters that give a good fit to the relation between x , downwind distance, and y , the horizontal width of the plume. But not all experts subscribe to this model. More complex alternatives have been proposed with different types of parameters. Asking an expert to provide judgments about a and b violates the first principle above. One cannot verify if the judgments are correct, experts may disagree on the definition of a and b , and experts who do not embrace the simple model will find the parameters not meaningful. It is very difficult to provide a value for something you do not believe exists.

The second requirement is that there is some knowledge that can be brought to bear on the event or quantity. For many issues, there is no directly applicable data so that data from analogs, models using social, medical or physical principles, etc., may form the basis for the judgments. If the basis for judgments is incomplete or sketchy, the experts should reflect this by expressing greater uncertainty in their judgments.

Once issues have been identified, it is necessary to develop a statement that presents the issue to the experts in a manner that will not color the experts' responses. This is called *framing* the issue. Part of framing is creating an unbiased presentation that is free of preconceived notions, political overtones, and discussions of consequences that might affect the response. Framing also provides a background for the question. Sometimes there are choices about whether certain conditions should be included or withheld from the analysis and whether the experts are to integrate the uncertainty about the conditions into their responses. For example, in a study of dry deposition of radioactivity, the experts were told that the deposition surface was northern European grassland, but they were not told the length of the grass which is thought to be an important determinant of the rate of deposition [1]. Instead, the experts were asked to treat the length of grass as an unknown and to incorporate any uncertainty that they might have into their responses. The experts should be informed about those factors that are considered to be known, those that are constrained in value, those that are uncertain, and, perhaps, those that should be excluded from their analyses.

Finally, once an issue has been framed and put in the form of statement to be submitted to the experts, it should be tested. The best way to do this testing is through a dry-run, with stand-in experts who have not been participants in the framing process. Although this seems like a lot of extra work, experience has shown that getting the issue right is both critical and difficult [2]. All too often, the expert's understanding of the question differs from what was intended by the analyst who drafted the question. It is also possible that the question being asked appears to be resolvable to the person who framed the question, but not to the expert who must respond.

Selecting the Experts

The identification of experts requires that one develop some criteria by which expertise can be measured. Generally, an expert is one who "has or is alleged to have superior knowledge about data, models and rules in a specific area or field" [3]. But measuring against this definition requires one to look at indicators of knowledge rather than knowledge *per se*. The following list contains such indicators:

- research in the area as identified by publications and grants
- citations of work
- degrees, awards, or other types of recognition
- recommendations and nominations from respected bodies and persons
- positions held
- membership or appointment to review boards, commissions, etc.

In addition to the above indicators, experts may need to meet some additional requirements. The expert should be free from motivational biases caused by economic, political, or other interest in the decision. The choice of whether to use internal or external experts often hinges on the appearance of motivational biases. Potential experts who are already on a project team may be much easier to engage in an expert judgment process, but questions about the independence of their judgments from project goals may be raised. Experts should be willing to participate and they should be accountable for their judgments [6]. This means that they should be willing to have their names associated with their specific responses. At times, physical proximity or availability will be an important consideration.

How the experts are to be organized also impacts the selection. Often, when more than one expert is used, the experts will be redundant of one another, meaning that they will perform the same tasks. In such a case, one should attempt to select experts with differing backgrounds, responsibilities, fields of study, etc., so as to gain a better appreciation of the differences among beliefs. In other instances, the experts will be complementary, each bringing unique expertise to the question. Here, they act more like a team and should be selected to cover the disciplines needed.

Some analyses undergo extreme scrutiny because of the public risks involved. This is certainly the case with radioactive waste disposal or purity of the blood supply. In such instances, the process for selecting (and excluding) experts should be transparent and well documented. In addition to written criteria, it may be necessary to isolate the project staff from the selection process. This can be accomplished by appointing an independent selection committee to seek nominations and make recommendations to the staff [7].

How many experts should be selected? Experience has shown that the differences among experts can be very important in determining the total uncertainty expressed about a question. Clemen and Winkler [8] examine the impact of dependence among experts using a normal model and conclude that three to five experts are adequate. Hora [9] created synthetic groups from the responses of real experts, and found that three to six or seven experts are sufficient, with little benefit from additional experts beyond that point. When experts are organized in groups, and each group provides a single response, this advice would apply to the number of groups. The optimal number of experts within a group has not been investigated and is likely to be dependent on the complexity of issues being answered.

The Quality of Judgments

Because subjective probabilities are personal and vary from individual to individual and from time to time, there is no “true” probability that one might use as a measure of the accuracy of a single elicited probability. For example, consider the question “what is the probability the next elected president of the United States is a woman?” Individuals may hold different probabilities or degrees of belief about this

event occurring. There is, however, no physical, verifiable probability that could be known but remains uncertain. The event will resolve as occurring or not but, will not resolve to a frequency or probability.

It is possible to address the goodness of probabilities, however. There are two properties that are desirable to have in probabilities:

- probabilities should be informative
- probabilities should authentically represent uncertainty.

The first property, being informative, means that probabilities closer to 0.0 or 1.0 should be preferred to those closer to 0.5 as the more extreme probabilities provide greater certainty about the outcome of an event. In a like manner, continuous probability distributions that are narrower or tighter convey more information than those that are diffuse. The second property, the appropriate representation of uncertainty, requires consideration of a set of assessed probabilities. For those events that are given an assessed probability of p , the relative frequency of occurrence of those events should approach p .

To illustrate this idea, consider two weather forecasters who have provided precipitation forecasts as probabilities. The forecasts are given to a precision of one digit. Thus a forecast of 0.2 is taken to mean that there is a 20% chance of precipitation. Forecasts from two such forecasters are shown in Figure 1.

Ideally, each graph would have a 45° line indicating that the assessed probabilities are faithful in that they correctly represent the uncertainty about reality. Weather Forecaster B’s graph shows a nearly perfect relation while the graph for the Forecaster A shows poorer correspondence between the assessed probabilities and relative frequencies with the actual frequency of rain exceeding the forecast probability. The graph is not even monotonic at the upper end.

Graphs showing the relation between assessed probabilities and relative frequencies are called *calibration graphs* and the quality of the relationship is loosely called *calibration* which can be good or poor [10]. Calibration graphs can also be constructed for continuous assessed distributions. Following [9], let $F_i(x)$ be a set of assessed continuous probability distribution functions and let x_i be the corresponding actual values of the variables. If an expert is perfectly calibrated, the cumulative probabilities of the actual values measured on each corresponding distributions

Figure 1 Calibration graph for two forecasters

function, $p_i = F_i(x)$, will be uniformly distributed on the interval $[0, 1]$. We can use the area between the 45° line of perfect calibration and the observed calibration curve as a measure of miscalibration for continuous probability assessments.

Although calibration is an important property for a set of probabilities or probability distributions to possess, it is not sufficient as the probabilities or probability distributions may not be informative. For example, in an area where it rains on 25% of the days, a forecaster who always predicts a 25% chance of rain will be perfectly calibrated but provide no information from day to day about the relative likelihood of rain. But information and calibration are somewhat at odds. Increasing the information by making probabilities closer to zero or one or by making distributions tighter may reduce the level of calibration.

One approach to measuring the goodness of probabilities is through scoring rules. Scoring rules are functions of the assessed probabilities and the true outcome of the event or value of the variable that measure the goodness of the assessed distribution and incorporate both calibration and information into the score. The term *strictly proper scoring function* refers to the property that the expected value of the function is maximized when the probabilities or probability functions to which the function is applied are identical to the probabilities or probability functions that are used to take the expectation. An example will clarify.

A simple strictly proper scoring rule for the assessed probability of an event is the Brier or quadratic rule [11]:

$$\begin{aligned} S(p) &= -(1-p)^2 \text{ if the event occurs} \\ &= -p^2 \text{ if the complement of the event} \\ &\quad \text{occurs} \end{aligned} \quad (1)$$

where p is the assessed probability. For any probability q , the mathematical expectation $E_q[S(p)] = -q(1-p)^2 - (1-q)p^2$ is maximized with respect to p by setting $p = q$. Thus, if an expert believes the probability is q , the expert will maximize the perceived expectation by responding with q . In contrast, the scoring rule $S(p) = -p$ if the event occurs and $S(p) = -(1-p)$, while intuitively pleasing, does not promote truthfulness. Instead, the expected score is maximized by providing a probability p of either 0.0 or 1.0 depending on whether q is less than or larger than 0.5. Winkler [12] provides a discussion of this Brier rule and other strictly proper scoring rules. See also [6, 10].

The concept of a strictly proper scoring rule can be extended to continuous distributions [13]. For example, the counterpart to the quadratic scoring rule for continuous densities is:

$$S[f(x), w] = 2f(w) - \int_{-\infty}^{\infty} f^2(x) dx \quad (2)$$

Expected scores can sometimes be decomposed into recognizable components. The quadratic rule for continuous densities can be decomposed in the following manner. Suppose that an expert's uncertainty

is correctly expressed through the density $g(x)$, but the expert responds with $f(x)$ either through inadvertence or intention. The expected score can be written as follows:

$$E_g \{S[f(x), w]\} = I(f) - C(f, g)$$

$$\text{where } I(f) = \int_{-\infty}^{\infty} f^2(x) dx \text{ and } C(f, g)$$

$$= 2 \int_{-\infty}^{\infty} f(x)[f(x) - g(x)] dx \quad (3)$$

$I(f)$ is the expected density associated with the assessed distribution and is a measure of information. $C(f, g)$ is a nonnegative function that increases as $g(x)$ diverges from $f(x)$. Thus $C(f, g)$ is a measure of miscalibration. Further discussion of decomposition can be found in [10, 14, 15]. Haim [16] provides a theorem that shows how a strictly proper scoring rule can be generated from a convex function. See also Savage [17].

Combining Expert Judgments

There are two situations that may require probability judgments to be combined. The first is when an expert has provided judgments about the elements of a model that result in a top event probability or distribution of a value. Examples of such decompositions include fault trees, event trees (*see Decision Trees*), and influence diagrams (*see Influence Diagrams*). With an event or probability tree, the recomposition can be accomplished by simple probability manipulations. In more complicated situations, you may need to employ simulation methods to obtain a top event probability or distribution for a quantity. This is a relatively straightforward process.

Judgments may also be combined across multiple experts. While using multiple experts to address a single question allows for a greater diversity of approaches and often provides a better representation of the inherent uncertainty, doing so creates the problem of having multiple answers when it would be convenient to have a single answer. If you decide to evaluate the risk model separately, using the judgments of each individual expert and you have multiple points in the model where different experts have given their judgments, the number of separate evaluations of the model is the product of the number of experts used at each place in the model and can

be very large. Aggregation of the judgments into a single probability or distribution avoids this problem.

There are two classes of aggregation methods, behavioral and mathematical. Behavioral approaches entail negotiation to reach a representative or consensus distribution. Mathematical methods, in contrast, are based on a rule or formula. The approaches are not entirely exclusive, however, as they may be both be used to greater or lesser degree to perform an aggregation.

You may be familiar with the “Delphi” technique, developed at the Rand Corporation in the 1960s by Norman Dalkey [18]. In the Delphi method, the interaction among the experts is tightly controlled. In fact, they do not meet face to face but remain anonymous to one another. This is done to eliminate the influence that one might have because of position or personality. The judgments are exchanged among the experts, along with the reasoning for the judgments. After viewing all the judgments and rationales, the experts are given the opportunity to modify their judgments. The process is repeated—exchanging judgments and revising them—until the judgments become static or have converged to a consensus. Often times, it will be necessary to apply some mathematical rule to complete the aggregation process.

Another behavioral approach is called the *nominal group* technique [19]. This technique, like Delphi, controls the interaction among experts. The experts meet and record their ideas or judgments in written form without discussion. A moderator then asks each expert to provide the idea or judgment and records this on a public media display such as a white board, flip chart, or computer screen. There may be several rounds of ideas/judgments which are then followed by discussion. The judgments/ideas are then ranked individually and anonymously by the experts and the moderator summarizes the rankings. This process can be followed by further discussion and reranking or voting on alternatives.

Kaplan [20] proposes a behavioral method for combining judgments through negotiation with a facilitator. The facilitator and experts meet together to discuss the problem. The facilitator’s role is to bring out information from the experts and interpret a “consensus body of evidence” that represents the aggregated wisdom of the group.

A wide range of mathematical methods for combining probability judgments have been proposed.

Perhaps the simplest and most widely used is a simple average termed the *linear opinion pool* [21]. This technique applies equally well to event probabilities and continuous probability densities or distributions. It is important to note that with continuous distributions, it is the probabilities not the values that are averaged. For example, it is tempting, given several medians, to average the medians, but this is not the approach we are referring to. An alternative to the simple average is to provide differential weights to the various experts, ensuring that the weights are nonnegative and sum to one. The values of the weights may be assigned by the staff performing the aggregation or they may result from some measure of the experts' performance. Cooke [6] suggests that evidence of the quality of probability assessments be obtained using training quizzes with questions from the subject matter area addressed by the expert. The experts are given weights based on the product of the p value for the χ^2 test of calibration and the information, as measured by the entropy in the assessments. A cutoff value is used so that poorly calibrated experts are not included in the combination.

The most elegant approach to combining judgments is provided by Morris [22, 23]. In his approach, a decision maker assigns a joint likelihood function to the various responses that a group of experts might provide and a prior distribution for the quantity or event in question. The likelihood function is conditional on the quantity or event of interest. Also see French [24] for a discussion of the axiomatic approaches to combining experts using a Bayesian approach. The decision maker can then develop the posterior distribution for the uncertain quantity or event using Bayes' theorem (*see Bayes' Theorem and Updating of Belief*).

Various mathematical methods for combining probability judgments have different desirable and undesirable properties. Genest and Zidek [25] describe the following property:

Strong set-wise function property

A rule for combining distributions has this property if the rule is a function only of the assessed probabilities and maps $[0, 1]^n \rightarrow [0, 1]$. In particular, the combination rule is not a function of the event or quantity in question.

This property, in turn, implies the following two properties:

Zero set property

If each assessor, $i = 1, \dots, n$ provides $P_i(A) = 0$, then the combined result, $P_c(A)$, should also concur with $P_c(A) = 0$.

Marginalization property

If a subset of events is considered, the marginal probabilities from the combined distribution will be the same as the combined marginal probabilities.

The strong set property also implies that the combining rule is a linear opinion pool or weighted average of the form

$$P_c(A) = \sum_{i=1}^n \alpha_i P_i(A) \quad (4)$$

where the weights, α_i , are nonnegative and sum to one.

Another property is termed the independence property is defined by:

$$P_c(A \cap B) = P_c(A)P_c(B) \quad (5)$$

whenever all experts assess A and B as independent events.

But the linear opinion pool does not have this property. Moreover, the linear opinion pool given above cannot be applied successfully to both joint probabilities and the component marginal and conditional probabilities. That is,

$$P_c(A|B)P_c(B) \neq \sum \alpha_i P_i(A|B)P_i(B) \quad (6)$$

except when one of the weights is one and all others are zero, so that one expert is a "dictator".

The strong set property was used by Dalkey [26] to provide an impossibility theorem for combining rules. Dalkey's theorem adopts seven assumptions that lead to the conclusion that while conforming to the seven assumptions, "there is no aggregation function for individual probability estimates which itself is a probability function". Boardley and Wolff [27] argue that one of these assumptions, the strong set property, is unreasonable and should not be used as an assumption.

While the linear rule does not conform to the independence property, its cousin, the geometric or logarithmic rule does. This rule is linear in the log probabilities and is given by

$$P_c(A) = k \prod_{i=1}^n P_i(A)^{\alpha_i} \text{ where } \alpha_i > 0, \sum_{i=1}^n \alpha_i = 1 \quad (7)$$

and k is a normalizing constant required because this rule does not have the strong set-wise property. The geometric rule also has the property of being externally Bayesian.

Externally Bayesian

The result of performing Bayes' theorem on individual assessments and then combining the revised probabilities is the same as combining the probabilities and then applying Bayes' theorem.

While the geometric rule is externally Bayesian, it is also dictatorial in the sense that if one expert assigns $P_i(A) = 0$, the combined result is necessarily $P_c(A) = 0$. We note that the linear opinion pool is not externally Bayesian.

It is apparent that all the desirable mathematical properties of combining rules cannot be satisfied by a single rule. The topic of selecting a combining method remains an open topic for investigation.

Expert Judgment Designs

In addition to defining issues and selecting and training the expert(s), there are a number of questions that must be addressed concerning the format for a probability elicitation. These include the following:

- the amount of interaction and exchange of information among experts;
- the type and amount of preliminary information that is to be provided to the experts;
- the time and resources that will be allocated to preparation of responses.
- What is the venue – the expert's place of work, the project's home, or elsewhere?
- Will there be training, what kind, and how will it be accomplished?
- Are the names of the experts to be associated with their judgments, and will individual judgments be preserved and made available?

The choices result in the creation of a design for elicitation that has been termed a *protocol*. Some protocols are discussed in [6, 28–30]. We briefly outline two different protocols that illustrate the range of options that have been employed in expert elicitation studies.

Morgan and Henrion [28] identify the Stanford Research Institute (SRI) assessment protocol as, historically, the most influential in shaping structured

probability elicitation. This protocol is summarized in [31]. It is designed around a single expert (subject) and single analyst engaged in a five-stage process detailed below:

- motivating – rapport with the subject is established and possible motivational biases explored;
- structuring – the structure of the uncertainty is defined
- conditioning – the subject is conditioned to think; fundamentally about his judgment and to avoid cognitive biases
- encoding – this is the actual quantification in probabilistic terms;
- verifying – checking for consistency, the responses obtained in the encoding.

The role of the analyst in the SRI protocol is primarily it to help the expert avoid psychological biases. The encoding of probabilities roughly follows a script. Stael von Holstein and Matheson [4] provide a script showing how an elicitation session might go forward.

The encoding stage for continuous variables is described in some detail in [31]. It begins with assessment of the extreme values of the variable. An interesting sidelight is that after assessing these values, the subject is asked to describe scenarios that might result in values of the variable outside of the interval and to provide a probability of being outside the interval. The process next goes to a set of intermediate values whose cumulative probabilities are assessed with the help of the probability wheel. The probability wheel provides a visual representation of a probability and its complement. Then, an interval technique is used to obtain the median and quartiles. Finally, the judgments are verified by testing for coherence and conformance with the expert's beliefs.

While the SRI protocol was designed for solitary experts, a protocol developed by Sandia Laboratories for the US Nuclear Regulatory Commission [5, 32] was designed to bring multiple experts together. The Sandia protocol consists of two meetings:

First meeting agenda

- presentation of the issues and background materials;
- discussion by the experts of the issues and feedback on the questions;

- a training session, including feedback on judgments.

The first meeting is followed by a period of individual study of approximately one month.

Second meeting agenda

- discussion by the experts of the methods, models, and data sources used;
- individual elicitation of the experts.

The second meeting is followed by documentation of rationales and opportunity for feedback from the experts. The final individual judgments are then combined using simple averaging to the final probabilities or distribution functions.

There are a number of significant differences between the SRI and Sandia protocols. First, the SRI protocol is designed for isolated experts while the Sandia protocol brings multiple experts together and allows them to exchange information and viewpoints. They are not allowed, however, to view or participate in the individual encoding sessions or comment on one another's judgments. Second, in the SRI protocol, it is assumed that the expert is fully prepared in that no additional study, data acquisition, or investigation is needed. Moreover, the SRI protocol places the analyst in the role of identifying biases and assisting the expert in counteracting these biases, while the Sandia protocol employs a structured training session to help deal with these issues. In both protocols, the encoding is essentially the same, although the probability wheel is today seldom employed by analysts. Third, the Sandia protocol places emphasis on obtaining and documenting multiple viewpoints which is consistent with the public policy issues addressed in those studies to which it had been applied.

Extreme Event Risk

“Extreme event” is a vague concept. It has a variety of formal definitions based on specific cases and contexts. Particular extreme events include, great earthquakes, floods, droughts, nuclear meltdowns, space shuttle losses, deaths, giant sea waves, stock crashes, landslides, storms, hurricanes, tornadoes, wildfires, and consequences of any of the preceding. The event of interest might be caused by man or by nature. The events occur in time or space. They may be purely random or somehow correlated. Their size might be measured in deaths or costs. The formal study of extreme event situations has led to important research results and management methods.

The concern of this encyclopedia is quantitative risk assessment and one specific definition of extreme event risk is,

Prob{certain performance variates exceed relevant critical values as a function of explanatories}

The performance variate might be a binary variable corresponding to whether or not the event occurs, or it might be the loss and damage associated with the event. In seismic engineering a concern is the damage resulting from forces generated by an earthquake in the physical component of a structure, say a nuclear reactor. In this case the models have become quite subtle. Three dimensional motion measured in historical earthquakes is employed in simulations. The performance variate might be the force being applied to a piece of piping. An explanatory might be the duration of the shaking of the earthquake. The duration of the applied forces is crucial. A very brief application may cause no damage, but a lengthy one may cause a catastrophe.

Phrased as above one has a statistics problem whose solutions may be based on stochastic modeling, data collection, and data analysis. Particular statistical methods prove helpful. These include: Bayes rule, influence diagrams, state space formulations, threshold models, aggregation, stratification, marked point process technology, trend models, cluster models, model validation, limit theorems, asymptotic approximations, and smoothing. The Poisson process plays an important role, but so too do renewal processes and marked point processes. These last have the form $\{t_j, M_j\}$ where t_j refers to the time of the

event and the mark M_j is associated information that might perhaps involve the past. The index of the *Encyclopedia of Environmetrics* [1], references these various concepts.

The subject matter of physics, chemistry, and engineering contributes to evaluations of risk as do the ideas of systems analysis. The latter includes box and arrow diagrams, simulation, decision tools, geographic information systems, and database management tools.

Typically, one seeks risk estimates for some future time interval. In seeking solutions to such a forecasting problem one might employ leading indicators. For example, in their concern with flooding in the Amazon city of Manaus, the authorities estimate the probability of eventual flooding during the year by the height of the river at the end of March and when time has passed the height at the end of April [2].

Desired products of an extreme event risk analysis include: hazard/risk maps, formulas, graphics, time plots, and forecasts. Risk probabilities, such as the one above, have been built into government regulations by NASA and the Nuclear Regulation Commission, for example.

Difficulties of the work include small data sets, time change and other inhomogeneities, poorly defined concepts, nonstandard situations, missing data, outliers, and measurement bias.

The demand for risk analyses is growing, in part because the costs of replacing destroyed structures are growing and in part because of the steady increase in the number of people living in hazardous areas.

Some details concerning the particular cases of seismic risk assessment, wildfire occurrence and flooding of the Amazon River are provided in [2]. Reference [3] has a chapter concerning seismic risk analysis. Risk assessment for space missions and hardware are discussed in [4]. References [5] and [6] present relevant statistical models and methods with the emphasis in [6] being on the insurance case. Catastrophe models are discussed in [7]. Reference [8] provides substantive and statistical material concerning climate research. Scholarly journals containing papers devoted to risk assessment include *Extremes*, *Geneva Papers on Risk and Insurance*, *Human and Environmental Risk Assessment*, *Natural Hazards*, *Risk Analysis*, *Risk and Reliability*, *Risk Research*, *Risk and Uncertainty*,

and *Stochastic Environmental Research and Risk Assessment*.

DAVID R. BRILLINGER

Extreme Value Theory in Finance

During the last decades, the financial market has grown rapidly. As a result, this has led to the demand and, consequently, to the development of risk-management systems. The internationally recognized regulatory concept is called *Basel II accord* (see **Credit Risk Models; Solvency; Credit Scoring via Altman Z-Score; Efficacy**), which suggests international standards for measuring the adequacy of a bank's risk capital. Hence, in any discussion on risk in finance, it is of importance to keep the Basel II accord in mind; see [1] for an interesting discussion on regulation of financial risk. Also, in the Basel II accord, the different aspects of financial risk are defined. We distinguish these as follows:

- *Market risk:* (see **Options and Guarantees in Life Insurance; Reinsurance; Value at Risk (VaR) and Risk Measures**) the risk that the value of an investment will decrease due to movements in market factors.
- *Credit risk:* (see **Informational Value of Corporate Issuer Credit Ratings; Credit Migration Matrices; Mathematical Models of Credit Risk; Default Risk; Credit Value at Risk**) the risk of loss due to a debtor's nonpayment of a loan (either the principal or interest (coupon) or both).
- *Operational risk:* (see **Nonlife Insurance Markets; Compliance with Treatment Allocation**) the risk of losses resulting from inadequate or failed internal processes, people and systems, or external events.

In this article, we discuss extreme value theory (EVT) (see **Individual Risk Models; Mathematics of Risk and Reliability: A Select History**) in general, and indicate how to use it to model, measure, and assess financial risk. On balance, EVT is a practical and useful tool for modeling and quantifying risk. However, it should, as with all model-based statistics, be used with care. For interesting reading of EVT and risk management, see [2, 3].

The structure of the article is as follows. In the section titled "Extreme Value Theory", we introduce basic concepts of EVT for independent and identically distributed (i.i.d.) data, independent of financial

applications. In the section titled "Financial Risk Management", we introduce financial market risk and describe how to model and analyze it with tools from EVT. Here, we also present methods for temporal-dependent financial time series and indicate multivariate modeling, both of which are important for risk management, in assessing joint losses at subsequent times and of different instruments in a portfolio. As the role of EVT in credit risk and operational risk has not yet been clarified and is under inspection, we have refrained from a thorough presentation. We would like, however, to refer to the papers [4–7] for an extreme value approach to credit risk, and to [8–11] for interesting developments in operational risk modeling. Further references can be found in these papers.

Extreme Value Theory

EVT is the theory of modeling and measuring events that occur with very small probability. This implies its usefulness in risk modeling, as risky events per definition happen with low probability. Textbooks on EVT include [12–17]. The book [12] treats extreme value statistics from a mathematical statistician's point of view with interesting case studies, and also contains material on multivariate extreme value statistics, whereas [13] lays greater emphasis on applications. The book [14] combines theoretical treatments of maxima and sums with statistical issues, focusing on applications from insurance and finance. In [15], EVT for stationary time series is treated. The monograph [16] is an extreme value statistics book with various interesting case studies. Finally, [17] is a mathematically well-balanced book aiming mainly at multivariate EVT based on multivariate regular variation. We also mention the journal *Extremes* which specializes on all probabilistic and statistical issues in EVT and its applications.

In EVT, there are two main approaches with their own strength and weakness. The first one is based on modeling the maximum of a sample (or a few largest values of a sample, called the upper order statistics) over a time period. In [14, Chapter 3], this approach is rigorously formulated based on the Fisher – Tippet theorem (see **Reliability of Large Systems**) going back to 1928. The second approach is based on modeling excess values of a sample over a threshold, within a time period. This approach is

called *peaks over threshold* or POT method and has been suggested originally by hydrologists.

Both approaches are equivalent by the Pickands – Balkema – de Haan theorem presented in [14, Theorem 3.4.5]. Statistics based on EVT has to use the largest (or smallest) values of a sample. They can be selected in different ways, and we assume at the moment that we have i.i.d. data. The first method is based on a so-called block maxima method, where data are divided into blocks, whose maxima are assumed to follow an extreme value distribution. The second method uses the joint distribution function of upper order statistics, and the third method uses the POT method, i.e., it invokes excesses over a high threshold. In this article, we focus on the POT method for two reasons. Firstly, there is a near consensus that its performance is better than other EVT methods for estimating quantiles; see e.g. [1]. Secondly, it can be extended easily to dependent data. This is also true for the block maxima method; however, the blocks have to be chosen so that the resulting block maxima are independent, so that maximum-likelihood estimation (MLE) can be applied. Further, the block maxima method invokes considerably less data than the POT method, which makes the POT method more efficient.

The existing software for the analysis of extreme events has been reviewed in [18], where a glossary of available packages can be found. We mention EVIS, which is written in SPlus, available at www.ma.h-w.ac.uk/~mcneil with the corresponding package EVIR based on R. Also, we recommend the package EVD, also based on R, which includes

programs for multivariate extreme value analysis at www.maths.lancs.ac.uk/~stephana. Finally, the MATLAB package EVIM is available at www.bilkent.edu.tr/~faruk.

The following introduction of the POT method is based on [19]. The POT method estimates a far out tail or a very high quantile, on the basis of extreme observations of a sample and consists of three parts. Each part is based on a probabilistic principle that is explained in the following paragraphs. Figure 1 serves as an illustration.

1. Point process of exceedances

Given a high threshold u_n , we index each observation of the sample $X_1, \dots, X_n$ exceeding u_n . (In Figure 1 these are observations 2, 3, 5, 6, 10, and 12.) To obtain a limit result, we let the sample size n tend to infinity and, simultaneously, the threshold u_n increase, in the correct proportion.

For i.i.d. data, each data point has the same chance to exceed the threshold u_n , the success probability being simply $P(X_i > u_n)$ for $i = 1, \dots, n$. Hence, the number of observations exceeding this threshold

$$\#\{i : X_i > u_n, i = 1, \dots, n\} = \sum_{i=1}^n I(X_i > u_n) \quad (1)$$

follows a binomial distribution with parameters n and $P(X_i > u_n)$. Here, $I(X_i > u_n) = 1$ or 0 , according as $X_i > u_n$ or $\leq u_n$. If for some $\tau > 0$

$$nP(X_i > u_n) \rightarrow \tau, \quad n \rightarrow \infty \quad (2)$$

then by the classical theorem of Poisson, the distribution of $\#\{i : X_i > u_n, i = 1, \dots, n\}$ converges to

Figure 1 Data $X_1, \dots, X_{13}$ with corresponding excesses $Y_1, \dots, Y_{N_u}$

a Poisson distribution with parameter τ . If $X_i, i = 1, \dots, n$, come from an absolutely continuous distribution, equation (2) is a rather weak condition: for all known absolutely continuous distributions and every $\tau > 0$, a suitable series (u_n) can be found (see e.g. [14, Chapter 3]). Indexing all points $\{i : X_i > u_n, i = 1, \dots, n\}$ in the interval $[0, n]$, the latter becomes larger and larger, whereas the indexed points become sparser and sparser (as the threshold u_n rises with n). A more economic representation is gained by not plotting the points on the interval $[0, n]$, but rather on the interval $[0, 1]$. An observation X_i exceeding u_n is then plotted not at i , but at i/n . If, for $n \in \mathbb{N}$, we define

$$N_n((a, b]) = \#\{i/n \in (a, b] : X_i > u_n, i = 1, \dots, n\} \quad (3)$$

for all intervals $(a, b] \subset [0, 1]$, then N_n defines a point process on the interval $[0, 1]$. This process is called the *time-normalized point process of exceedances*. Choosing u_n such that equation (2) holds, the series N_n of point processes converges (as $n \rightarrow \infty$) in distribution to a Poisson process with parameter τ . For the measure theoretical background on convergence of point processes, see e.g. [14, Chapter 5].

2. The generalized Pareto distribution (see Extreme Values in Reliability)

For the exceedances of a high threshold, we are not only interested in when and how often they occur, but also in how large the excess $X - u | X > u$ is. (In Figure 1 the excesses are labeled $Y_1, \dots, Y_{N_u}$, and the number of exceedances is $N_u = 6$.) Under condition (2) it can be shown that for a measurable positive function a ,

$$\lim_{u \rightarrow \infty} P\left(\frac{X - u}{a(u)} > y \mid X > u\right) = (1 + \xi y)^{-1/\xi} \quad (4)$$

if the left-hand side converges at all. For $\xi = 0$, the right-hand side is interpreted as e^{-y} . For all $\xi \in \mathbb{R}$ the right-hand side is the tail of a distribution function, the so-called *generalized Pareto distribution*. If $\xi \geq 0$ the support of this distribution is $[0, \infty)$, for $\xi < 0$ the support is a compact interval. The case $\xi < 0$ is of no interest for our applications, and therefore, not considered.

3. Independence

Finally, it can be shown that the point process of exceedances and the excesses, that is, the sizes of the exceedances, are in the limit independent.

How can these limit theorems be used to estimate tails (see **Enterprise Risk Management (ERM)**) and quantiles?

The following paragraph illustrates the POT method for a given sample $X_1, \dots, X_n$. For a high threshold u , we define

$$N_u = \#\{i : X_i > u, i = 1, \dots, n\} \quad (5)$$

We refer to the excesses of $X_1, \dots, X_n$ as $Y_1, \dots, Y_{N_u}$, as indicated in Figure 1. The tail of F is denoted by $\bar{F} = 1 - F$. Defining $\bar{F}_u(y) = P(Y_1 > y | X > u)$ yields

$$\bar{F}_u(y) = P(X - u > y | X > u) = \frac{\bar{F}(u + y)}{\bar{F}(u)}, \quad y \geq 0 \quad (6)$$

Consequently, we get

$$\bar{F}(u + y) = \bar{F}(u) \bar{F}_u(y), \quad y \geq 0 \quad (7)$$

An observation larger than $u + y$ is obtained if an observation exceeds u , i.e., an exceedance is required, and if, furthermore, such an observation has an excess over u that is also greater than y . An estimator of the tail (for values greater than u) can be obtained by estimating both tails on the right-hand side of equation (7).

This is done by exploiting (1–4) above.

We estimate $\bar{F}(u)$ by its empirical counterpart

$$\widehat{\bar{F}}(u) = \frac{1}{n} \sum_{i=1}^n I(X_i > u) = \frac{N_u}{n} \quad (8)$$

Then, we approximate $\bar{F}_u(y)$ by the generalized Pareto distribution, where the scale function $a(u)$ has to be taken into account. The latter is integrated into the limit distribution as a parameter. This gives

$$\bar{F}_u(y) \approx \left(1 + \xi \frac{y}{\beta}\right)^{-1/\xi} \quad (9)$$

where ξ and β have to be estimated (by $\hat{\xi}$ and $\hat{\beta}$). (Note that $\beta = \beta(u)$ is a function of u .) This results,

for given u , in the following tail estimator:

$$\bar{F}(u + y) = \frac{N_u}{n} \left(1 + \hat{\xi} \frac{y}{\hat{\beta}} \right)^{-1/\hat{\xi}}, \quad y \geq 0 \quad (10)$$

By inversion, one obtains for a given $\alpha \in (0, 1)$, an estimator of the α -quantile of the form

$$\hat{x}_\alpha = u + \frac{\hat{\beta}}{\hat{\xi}} \left(\left(\frac{n}{N_u} (1 - \alpha) \right)^{-\hat{\xi}} - 1 \right) \quad (11)$$

Finding the threshold u is important, but by no means trivial. It is a classical variance-bias problem, made worse by the small sample of rare events data. The choice of the threshold is usually based on an extended explorative statistical analysis; cf. [14, Section 6.2] or [13, Chapter 4]. Once the threshold is found, parameter estimation can be performed by maximum likelihood. The seminal paper [20] shows that MLEs are asymptotically normal, provided that $\xi > -0.5$, and derives the asymptotic covariance matrix of the estimators; see [14, Section 6.5] or [13, Chapter 4]. This allows also to calculate confidence intervals. Alternatively, they can also be obtained by the profile likelihood method; see [13]. There are algorithms on adaptive threshold selection, some asymptotically optimal, in settings similar to the POT method, see e.g. [12, Section 4.7]. However, to apply such black box methods can be dangerously misleading (see the Hill horror plot in [14, Figure 4.1.13]), and we view such automatic methods as a complementary tool, which can be helpful in finding an appropriate threshold, but which should not be used stand alone.

Financial Risk Management

We recall that market risk is the risk that the value of an investment decreases due to movements in market factors. Examples include equity risk, interest rate risk, currency risk, and commodity risk. The most common risk measure in the finance industry is the *value at risk* (VaR) (see **Risk Measures and Economic Capital for (Re)insurers; Credit Migration Matrices; Value at Risk (VaR) and Risk Measures**), which is also recommended in the Basel II accord. Consider the loss L of a portfolio over a given time period Δ , then VaR is a risk statistic that measures the risk of holding the portfolio for the time

period Δ . Assume that L has distribution function F_L , then we define VaR at level $\alpha \in (0, 1)$ as

$$\begin{aligned} \text{VaR}_\alpha^\Delta(L) &= \inf\{x \in \mathbb{R} : P(L > x) \leq 1 - \alpha\} \\ &= \inf\{x \in \mathbb{R} : F_L(x) \geq \alpha\} \end{aligned} \quad (12)$$

Typical values of α are 0.95 and 0.99, while Δ usually is 1 or 10 days. For an overview on VaR in a more economic setting we refer to [21].

Although intuitively a good concept, VaR has met criticism from academia and practice because of some of its theoretical properties and its nonrobustness in statistical estimation. On the basis of an axiomatic approach, Artzner *et al.* [22] suggest so-called coherent risk measures, which excludes VaR as it is, in general, not subadditive. An alternative set of axioms has been suggested in [23], leading to convex risk measures, motivated by the economic fact that risk may not increase linearly with the size of the portfolios.

A risk measure closely related to VaR, which is coherent, is the expected shortfall (ES), also known as *conditional VaR* (CVaR), which is defined as the expected loss given that we have a loss larger than VaR. Assume that $E[|L|] < \infty$, then ES is defined as

$$ES_\alpha^\Delta(L) = E[L | L > \text{VaR}_\alpha^\Delta(L)] \quad (13)$$

Provided the loss distribution is continuous, then

$$ES_\alpha^\Delta(L) = \frac{1}{1 - \alpha} \int_\alpha^1 \text{VaR}_x^\Delta(L) \, dx \quad (14)$$

Although ES is a more informative risk measure than VaR, it suffers from even higher variability, as we use information very far out in the tail. For a discussion on the problematic description of complex risk with just one single number, we refer to [3].

As VaR and ES are, per definition, based on a high quantile, EVT is a tailor-made tool for estimating both. Instead of considering the whole distribution, estimation is based on the tail of the loss distribution in the context of the acronym *letting the tail speak for itself*. This is the only way of obtaining an estimator based on the relevant data for an extreme event. We concentrate here on the estimation procedure using the POT method, as described in the section titled “Extreme Value Theory”.

Concretely, using the generalized Pareto distribution, $\text{VaR}_\alpha^\Delta(L)$ is estimated as the α -quantile of the log-differences (called logreturns) of the portfolio loss process $(L_t)_{t \in \mathbb{N}_0}$ in a time interval of length Δ .

The logreturns are assumed to constitute a stationary time series, then the data used for estimation are given by

$$X_t^\Delta = \log(L_t) - \log(L_{t-\Delta}), \quad t = \kappa \Delta, \kappa \in \mathbb{N}_0 \quad (15)$$

Now, using equation (11) for a well-chosen threshold $u > 0$, we obtain an estimate for the quantile of the logreturn loss distribution as

$$\widehat{\text{VaR}}_\alpha(X^\Delta) = u + \frac{\hat{\beta}}{\hat{\xi}} \left(\left(\frac{n}{N_u} (1 - \alpha) \right)^{-\hat{\xi}} - 1 \right) \quad (16)$$

Similarly, ES can be estimated, provided that the logreturns have finite expectation ($\xi < 1$), and we obtain

$$\widehat{\text{ES}}_\alpha(X^\Delta) = \frac{\widehat{\text{VaR}}_\alpha(X^\Delta)}{1 - \hat{\xi}} + \frac{\hat{\beta} - \hat{\xi}u}{1 - \hat{\xi}} \quad (17)$$

In a bank, usually, a daily VaR is estimated, i.e., $\Delta = 1$ day based on daily logreturns. However, according to the Basel II accord $\Delta = 10$ days has to be estimated as well. This is statistically problematic as one needs a very long time series to get good estimates, which, on the other hand, puts stationarity to the question. To avoid this problem, and also to avoid multiple estimation, one often uses a scaling rule,

$$\begin{aligned} \widehat{\text{VaR}}_\alpha(X^\Delta) &= \Delta^\kappa \widehat{\text{VaR}}_\alpha(X^1) \quad \text{and} \\ \widehat{\text{ES}}_\alpha(X^\Delta) &= \Delta^\kappa \widehat{\text{ES}}_\alpha(X^1) \end{aligned} \quad (18)$$

Here, typically, $\kappa = 0.5$ is chosen, the so-called square root scaling rule, which is based on the central limit theorem; see [1] for a discussion on different values of κ . Applying such a scaling rule as in equation (18) can, however, be grossly misleading as realistic financial models usually do not allow for such naive scaling; cf. [24] for an example.

Time Series Approach

A stylized fact of financial logreturns is that they are seemingly uncorrelated, but the serial correlation of absolute or squared logreturns is significant. This is because of the empirical fact that a large absolute movement tends to be followed by a large absolute movement. One can view this as a varying temperature of the market introducing dependence into the data. In a naive EVT approach, one ignores this effect and, therefore, produces estimators with nonoptimal performance.

To estimate VaR and/or ES for temporally dependent data two approaches have been suggested in the literature. The first approach is called *unconditional* VaR or ES estimation and is based on a POT method, where possible dependence is taken into account. In such models, provided they are stationary, the POT method presented by (1–4) in the section titled “Extreme Value Theory”, has to be modified to account for possible clustering in the extremes. The limiting point process of (3) can, by dependence, become a marked Poisson process. Exceedances over high thresholds (see **Extreme Values in Reliability**) appear in clusters, so that a single excess as in the Poisson process, turns into a random number of excesses, whose distribution is known for certain models; see [15] or [14, Chapter 8], for the theoretical basis and [25, 26], for examples. As a consequence, the maximum value of a large sample of size n from such a dependent model behaves like the maximum value of a smaller sample size $n\theta$ for some $\theta \in (0, 1)$ of an i.i.d. sample with the same marginal distribution. The parameter θ is called *extremal index* and can, under weak regularity conditions, be interpreted as the inverse of the mean cluster size. This parameter enters into the tail and quantile estimators (equations 10 and 11), which become, for a high threshold $u > 0$,

$$\bar{F}(u + y) = \frac{N_u}{n\theta} \left(1 + \hat{\xi} \frac{y}{\hat{\beta}} \right)^{-1/\hat{\xi}}, \quad y \geq 0 \quad (19)$$

respectively, for $\alpha \in (0, 1)$,

$$\hat{x}_\alpha = u + \frac{\hat{\beta}}{\hat{\xi}} \left(\left(\frac{n\theta}{N_u} (1 - \alpha) \right)^{-\hat{\xi}} - 1 \right) \quad (20)$$

The parameter θ has to be estimated from the data and is again, of course, highly dependent of the threshold u ; see [14, Section 8.1], for details and estimation procedures. New methods have been suggested in [27, 28].

The second approach is called *conditional* or *dynamic* VaR (see **Equity-Linked Life Insurance; From Basel II to Solvency II – Risk Management in the Insurance Sector; Credit Migration Matrices**) or *ES estimation*. The most realistic models introduce stochastic volatility (see **Risk-Neutral Pricing: Importance and Relevance; Numerical Schemes for Stochastic Differential Equation Models; Volatility Smile**) and model a portfolio’s daily logreturns by

$$X_t = \mu_t + \sigma_t Z_t, \quad t = 1, \dots, n \quad (21)$$

where σ_t is the stochastic volatility, μ_t is the expected return, and Z_t is a random variable with mean zero and variance one. It starts by estimating μ_t and σ_t , usually by means of quasi-maximum likelihood (see **Statistics for Environmental Mutagenesis; Repeated Measures Analyses**), and applies the classical POT method from the section titled “Extreme Value Theory” to the residuals $\hat{Z}_t = (X_t - \hat{\mu}_t)/\hat{\sigma}_t$. The residuals $\hat{Z}_t$ are sometimes called devolatilized logreturns. We obtain for a given time period Δ ,

$$\widehat{\text{VaR}}_\alpha(X^\Delta) = \hat{\mu}_{t+\Delta} + \hat{\sigma}_{t+\Delta} \widehat{\text{VaR}}_\alpha(Z^\Delta) \quad (22)$$

and

$$\widehat{\text{ES}}_\alpha(X^\Delta) = \hat{\mu}_{t+\Delta} + \hat{\sigma}_{t+\Delta} \widehat{\text{ES}}_\alpha(Z^\Delta) \quad (23)$$

The most prominent conditional mean and variance model for μ_t and σ_t is the ARMA-(G)ARCH model which considers the mean to be an ARMA process and the volatility to be a (G)ARCH process, see [29]. It is worth mentioning that Robert F. Engle received the Sveriges Riksbank Prize in Economic Sciences in Memory of Alfred Nobel in 2003 for his development of the (G)ARCH models. For a successful implementation of estimating VaR and ES using the ARMA-(G)ARCH model, we refer to the explanatory paper [30]. It exemplifies that an AR-(G)ARCH model, together with the generalized Pareto distribution for the residuals, produces very accurate VaR and ES estimates.

Financial market data of liquid markets are tick-by-tick data, where each tick corresponds to a transaction. Such data are also termed high-frequency data and have been in the focus of research in recent years. The accessibility of high-frequency data has lead to the development of continuous-time financial models, see e.g. [31, 32] for two different models and [33] for a comparison. VaR estimation based on high-frequency data has been considered in [34], estimating VaR on different time frames using high-frequency data; see also [35] for a discussion on extreme returns of different time frames.

Multivariate Issues

Often, when modeling financial risk, one investigates the development of a portfolio’s logreturns, aggregating different risk factors. This prevents the possibility of tracking joint large losses, which may indeed lead to complete disaster. Consequently, one should model a portfolio as a multivariate random vector. Unfortunately, in financial applications, this leads easily to a

very high-dimensional problem, and modeling of the dependence structure could be very difficult, or even impossible. One way out is to use comparably few selected risk factors, or to group assets in different sectors or geographical regions.

Multivariate EVT (see **Individual Risk Models; Multivariate Reliability Models and Methods; Mathematics of Risk and Reliability: A Select History; Copulas and Other Measures of Dependence**) provides the theoretical background to model and analyze joint extreme events by concentrating on dependence in extreme observations. An indication of extreme dependence in financial data is the well-known fact that market values tend to fall together in a market crash. Multivariate EVT makes a contribution to this problem by offering a tool to model, analyze, and understand the extreme dependence structures; see Figure 2 to indicate that the commonly used normal model does not capture joint extreme events.

In multivariate EVT, there are mainly two approaches. The first one utilizes multivariate regular variation. This approach is based on the fact that marginal models for high risk data are very well modeled by Pareto-like models, whose tails decrease like $P(X > x) = x^{-\alpha} \ell(x)(1 + o(1))$ as $x \rightarrow \infty$ for some function ℓ satisfying $\lim_{t \rightarrow \infty} \ell(xt)/\ell(t) = 1$, for all $x > 0$. Given that all marginal distributions in the portfolio have such tails with the same α , extreme dependence can be modeled by the so-called spectral measure. Indeed, a multivariate, regularly varying, random vector has univariate, regularly varying, distribution tails along each direction from the origin and a measure, the spectral measure, which describes the extreme dependence. More precisely, a random vector X in $\mathbb{R}^d$ is *regularly varying with index* $\alpha \in [0, \infty)$ and spectral measure σ on the Borel sets of the unit sphere $\mathbb{S}^{d-1} := \{z \in \mathbb{R}^d : \|z\| = 1\}$, if for all $x > 0$

$$\frac{P(\|X\| > xt, X/\|X\| \in \cdot)}{P(\|X\| > t)} \xrightarrow{v} x^{-\alpha} \sigma(\cdot) \quad t \rightarrow \infty \quad (24)$$

where $\|\cdot\|$ denotes any norm in $\mathbb{R}^d$ and $\xrightarrow{v}$ denotes vague convergence; for details see [17, 36–38] and references therein. This approach has been applied, for instance, in [39, 40] to analyze high-frequency foreign exchange (FX) data.

The second approach is based on Pickands’ representation of a multivariate extreme value distribution, which aims at the asymptotic frequency for

Figure 2 Bivariate stock data *versus* simulated normal random numbers with same (estimated) means and variances

joint large values in a portfolio. For two risk factors or assets X and Y with distribution functions F and G , respectively, the risk manager is interested in $P(X > x \text{ or } Y > y)$ for x, y large. This is measured by the quantity $(x \vee y = \max(x, y))$ and $x \wedge y = \min(x, y)$.

$$\begin{aligned} \Lambda(x, y) &= \lim_{n \rightarrow \infty} nP \left(F(X) > 1 - \frac{x}{n} \text{ or } G(Y) > 1 - \frac{y}{n} \right) \\ &= \int_0^{\pi/2} \left(\frac{x}{1 \vee \cot \theta} \vee \frac{y}{1 \vee \tan \theta} \right) \Phi(d\theta) \end{aligned} \quad (25)$$

and the limit exists under weak regularity conditions with finite measure Φ on $(0, \pi/2)$ satisfying

$$\int_0^{\pi/2} \frac{1}{1 \wedge \cot \theta} \Phi(d\theta) = \int_0^{\pi/2} \frac{1}{1 \wedge \tan \theta} \Phi(d\theta) = 1 \quad (26)$$

The measure Φ has to be estimated from the data, which can be done parametrically and nonparametrically. As it is more intuitive to estimate (dependence)

functions instead of measures, *Pickands' dependence function* and a so-called tail-dependence function have been introduced. They both aim at assessing joint extreme events. For Pickands' dependence function we refer to [13, Chapter 8], and [12, Section 8.2.5], where parametric and nonparametric estimation procedures have been suggested and investigated. The tail-dependence function has been proposed and estimated nonparametrically in [41]. Nonparametrical approaches are based on fundamental papers like [42]; for further references, see this paper.

Estimates as above can be improved for elliptical distributions or even for distributions with elliptical copula; cf. [43, 44]. The tail-dependence function is also invoked in [45], which includes an in depth analysis of multivariate high-frequency equity data.

Multivariate analogs to the POT method of the section "Extreme Value Theory" have been developed. We refer to [12, 13] for further details. Multivariate generalized Pareto distributions are natural models for multivariate POT data; see [46] and further references therein.

Extreme Values in Reliability

Extreme value (EV) theory (*see Large Insurance Losses Distributions; Multistate Systems*) is basically developed from the maximum domain of attraction condition ([1, 2]; *see* [3, 4] for a recent introduction to the theory). It states that the distribution of the maximum (or the minimum) of a sample can be approximated, under very general conditions, by any one of the EV distributions, Gumbel (also called *Type I*), Fréchet (*Type II*), or Weibull (*Type III*); *cf.* the section titled “The Class of EV Distribution” (*see Copulas and Other Measures of Dependency*) for more details.

Alternatively, one can consider the sample of the exceedances. Given a high value (usually called the *threshold*), the exceedances are the positive differences (*see Structural Reliability*) between the sample values and the threshold. Then, the generalized Pareto (GP) distribution approximates the (conditional) distribution of the exceedances properly normalized; *cf.* the section titled “GP Distribution and Peaks over Threshold”.

For instance, in corrosion analysis, pits of larger depth are of primary interest as pitting corrosion can lead to the failure of metallic structures such as tanks and tubes. From the maximum domain of attraction condition, the class of EV distributions are the natural distributions to approximate to the distribution of the maximum pit depth. Thus, e.g., estimation procedures for parameters related to the distribution of the maximum such as the EV index (in the section titled “EV Index Estimation”), or related to the tail of the underlying distribution such as high quantiles (in section “Return Period and High-Quantile Estimation”), or failure probabilities (in section “Mean Excess Function, Model Fitting and Estimation”), are well studied.

The present discussion only deals with the simplest framework, univariate EV theory and samples $X_1, X_2, \dots, X_n$ supposedly drawn from independent and identically F distributed random variables. Some of the concepts discussed below have natural extensions to higher dimensions. For more on multivariate or infinite dimensional EV theory, *see* [4]. For EV theory concerning nonindependent

or nonidentically distributed random variables *see*, e.g., [4, 5].

The Class of EV Distributions

A distribution function F is said to be in the domain of attraction of some EV distribution (and consequently the maximum domain of attraction condition holds), if one can find real sequences $a_n > 0$ and b_n such that

$$\lim_{n \rightarrow \infty} \text{Prob} \left(\frac{\max(X_1, X_2, \dots, X_n) - b_n}{a_n} \leq x \right) = G(x) \quad (1)$$

for each continuity point x of G , and G is a nondegenerate distribution function. Then it is known that G must be one of the *EV distributions*, in the von Mises parameterization given by,

$$G_\gamma(x) = \exp \left(-(1 + \gamma x)^{-1/\gamma} \right), \quad 1 + \gamma x > 0 \quad (2)$$

(for $\gamma = 0$ the right-hand side should be interpreted as $\exp(-e^{-x})$) with γ real, a shape parameter called the *EV index*. Nonstandard forms are simply $G_\gamma(\sigma x + \mu)$ with $\sigma > 0$ the scale parameter and μ the location parameter.

The following distributions are often encountered as an alternative parameterization, corresponding respectively to the subclasses $\gamma = 0$, $-\gamma = 1/\alpha > 0$, and $\gamma = 1/\alpha > 0$: *double-exponential* or *Gumbel distribution*,

$$\Lambda(x) = \exp(-e^{-x}) \quad \text{for all real } x \quad (3)$$

Reverse Weibull distribution,

$$\Psi_\alpha(x) = \begin{cases} \exp(-(-x)^\alpha), & x < 0 \\ 1, & x \geq 0 \end{cases} \quad (4)$$

and *Fréchet distribution*,

$$\Phi_\alpha(x) = \begin{cases} 0, & x \leq 0 \\ \exp(-x^{-\alpha}), & x > 0 \end{cases} \quad (5)$$

Distributions in the Gumbel domain of attraction are, e.g., normal, log-normal, gamma, exponential and, of course, the Gumbel itself. Distributions in the reverse Weibull domain of attraction are, e.g., beta and uniform. Distributions in the Fréchet domain of attraction are, e.g., Cauchy and Pareto.

Figure 1 Gumbel Q–Q plot

Main properties distinguishing the three subclasses (equations (3)–(5)) are:

- For $\gamma = 0$ the right endpoint of the limiting distribution, i.e., $\lim_{x \rightarrow \infty} \Lambda(x)$, equals infinity, and the distribution is rather light tailed (it decays exponentially). All moments are finite.
- The reverse Weibull distribution ($\gamma < 0$) has right endpoint equal to $-1/\gamma$, it decays as a power law, and all moments exist.
- The right endpoint of the Fréchet distribution is infinity and the distribution has a rather heavy right tail, decaying as a power law. Moments of order greater than or equal to $1/\gamma$ do not exist.

Since $\min(X_1, X_2, \dots, X_n) = -\max(-X_1, -X_2, \dots, -X_n)$, EV distributions for the minimum have a one-to-one correspondence with the ones for the maximum, say $G^*(x) = 1 - G(-x)$, for all x . For instance, the *Weibull distribution* is one of the possible limiting distributions for conveniently normalized minima (i.e., when $\gamma < 0$),

$$\Psi_\alpha^*(x) = 1 - \Psi_\alpha(-x) = \begin{cases} 0, & x \leq 0 \\ 1 - \exp(-x^\alpha), & x > 0 \end{cases} \quad (6)$$

Application 1: The Gumbel Model for Maximum Pit Depth

The observations (in micrometers) correspond to the maximum pit depth developed on $N = 10$ metal

samples after 1 month exposure to tap water [6]: (570, 620, 640, 640, 700, 740, 780, 810, 840, 910). We shall fit a model to the maxima, and from it estimate the return period and high quantiles.

Gumbel Q–Q Plot and Model Fitting

The Gumbel Q–Q plot provides a quick “visual selection method” for distribution fitting. Plotting the ordered sample against the Gumbel quantiles $\Lambda^{-1}(i/(N+1)) = (-\log(-\log(i/11)))$, $i = 1, \dots, N$, the observations fit quite well in a straight line (cf. Figure 1). Generally one decides for the Gumbel, Weibull, or Fréchet distributions if the points follow approximately a straight line, convex or concave curves, respectively.

More advanced tests can also be applied. For instance, for the “common” likelihood ratio test, which in this case tests within the EV model, $H_0 : \gamma = 0$ versus $H_1 : \gamma \neq 0$, we obtained a p value of 0.69, hence inducing for not rejecting the null hypothesis. Tests for checking the EV condition can be found in [4]. Specific tests for selecting EV distributions within the maximum domain of attraction is, e.g., the Hasofer and Wang test [7]. A class of goodness-of-fit tests for the Gumbel model was investigated by Stephens [8].

Now back to the application, taking the Gumbel as the parametric model fitted to the distribution of the maximum pit depth, the maximum likelihood estimates of the location and scale parameters are,

respectively, $\mu = 696.43$ and $\sigma = 52.13 \mu\text{m}$. These estimates were obtained numerically as there are no explicit analytical expressions for the maximum likelihood estimators in the Gumbel model. Parameter estimation for EV distributions is discussed, e.g., in [3, 9]; [10], a paper discussing on available software for EV theory.

Return Period and High-Quantile Estimation

The return period (*see Bayesian Statistics in Quantitative Risk Assessment*) at a level u say, is a common characteristic to estimate in these kinds of problems. In the example, it corresponds to the number of coupons that on an average must be exposed to tap water in order to obtain a pit depth greater than u . Solely based on the sample, we would have 10 coupons (the sample size) exposed for the return period at $850 \mu\text{m}$ (the sample maximum). Then note that the sample is of no use anymore if u is larger than the sample maximum. Yet, using the fitted parametric model, extrapolation beyond the range of the available data is possible. From the fitted Gumbel distribution one obtains for the return period at u ,

$$\begin{aligned} \frac{1}{1 - F(u)} &\approx \frac{1}{1 - \Lambda_{\hat{\mu}, \hat{\sigma}}(u)} \\ &= \frac{1}{1 - \exp(-e^{-(u-696.43)/52.13})} \end{aligned} \quad (7)$$

The reverse problem of estimating the level u for a mean of C coupons exposed to corrosion, leads to a major problem in EV statistics, high-quantile estimation, high meaning that estimates may be beyond the sample maximum. Again using the fitted model information, in this case the inverse function of the fitted distribution, we get the estimator

$$\begin{aligned} \hat{u} &= \Lambda_{\hat{\mu}, \hat{\sigma}}^{\leftarrow}(1 - 1/C) \\ &= 696.43 - 52.13 \times \log(-\log(1 - 1/C)) \end{aligned} \quad (8)$$

For instance, $C = 100$ corresponds to the 0.99-quantile estimate, $\hat{u} = \Lambda_{\hat{\mu}, \hat{\sigma}}^{\leftarrow}(0.99) = 936.24 \mu\text{m}$. Note that this value is beyond 910, the sample maximum.

GP Distributions and Peaks over Threshold

The maximum domain of attraction condition is equivalent to the following: there exists a positive real function f such that

$$\lim_{t \rightarrow x^*} \frac{\text{Prob}(X > t + xf(t))}{\text{Prob}(X > t)} = (1 + \gamma x)^{-1/\gamma} \quad (9)$$

for all x for which $1 + \gamma x > 0$, and $x^* = \sup\{x : F(x) < 1\}$ denotes the right endpoint of the underlying distribution. The left-hand side of equation (9) gives the *generalized Pareto (GP) distributions*,

$$H_{\gamma}(x) = 1 - (1 + \gamma x)^{-1/\gamma} \quad (10)$$

(for $\gamma = 0$ the right-hand side should be interpreted as $1 - e^{-x}$) for $x > 0$ if $\gamma \geq 0$ and $0 < x < -1/\gamma$ otherwise, as the class of distributions to approximate to the conditional distribution of $(X - t)/f(t)$ given X is above the threshold t . The parameter γ is the same EV index as in the EV distributions.

Particular cases of GP distributions are when $\gamma = 0$, with the exponential distribution, $\gamma > 0$ with Pareto distributions, and $\gamma = -1$ with the uniform distribution. Nonstandard forms are straightforward as in the EV class. A characteristic property of the GP distribution is its stability with respect to conditioning: if X is a random variable GP distributed, then the conditional distribution of $X - t$ given $X > t$, for any t in the range of possible values of X , is also GP with the same EV index.

Estimation of the GP parameters, in a parametric setting, is well studied (e.g., [9]). The semiparametric approach connected with equation (9), *peaks over threshold (POT)*, (*see Extreme Value Theory in Finance*) is more interesting to EV analysis. In this case, statistical inferences in the tail of distributions are based on the excesses over a high threshold whose distribution is approximated by a GP distribution.

EV Index Estimation

EV index estimation is important in EV statistics since any inference concerning tails of distributions necessarily involves the estimation of γ (recall that the approximate distributions depend on this parameter).

For a sample of size n , define the order statistics (*see Uncertainty Analysis and Dependence Modeling*) as $X_{1,n} \leq X_{2,n} \leq \dots \leq X_{n,n}$. It is common in

Table 1 Fatigue data, sample size equal to 49

1.051	4.921	7.886	10.861	13.520	1.337	5.445	8.108	11.026
13.670	1.389	5.620	8.546	11.214	14.110	1.921	5.817	8.666
11.362	14.496	1.942	5.905	8.831	11.604	15.395	2.322	5.956
9.106	11.608	16.179	3.629	6.068	9.711	11.745	17.092	4.006
6.121	9.806	11.762	17.568	4.012	6.473	10.205	11.895	17.568
4.063	7.501	10.396	12.044	—	—	—	—	—

**Figure 2** EV index estimation for the fatigue data: dotted line for Pickands, dashed for moment and straight for PWM

EV theory to use only the k th highest order statistics, $X_{n-k,n} \leq \dots \leq X_{n,n}$, to estimate γ , which can be seen as an application of the POT approach with the random threshold $t = X_{n-k,n}$. Solutions of approximate maximum likelihood estimators require numerical methods and are theoretically well known. Among estimators with explicit formulas is Hill's estimator [11], $\hat{\gamma} = k^{-1} \sum_{i=0}^{k-1} \log X_{n-i,n} - \log X_{n-k,n}$, very frequently cited though it is consistent only for positive values of γ (see below for other estimators and properties).

Estimation of the EV index is vastly studied with known theoretical properties where, for instance, confidence intervals and testing may be straightforward (cf. [3, 4]).

Application 3: GP in a Fatigue Problem

Next we apply the POT approach to the fatigue data for the Kevlar/Epoxy strand lifetime (in hours) at a stress level equal to 70% [12] (cf. Table 1). With this kind of data one is usually interested in the left tail of the underlying distribution. The GP distribution is applicable as in equation (9), by taking the symmetric

sample, which transforms the lower tail into the upper tail.

Mean Excess Function, Model Fitting, and Estimation

Since GP distributions are the only distributions where the *mean excess function* (also called *mean residual life function*), $E(X - t | X > t)$, $0 \leq t \leq x^*$, is a straight line, its empirical version provides a common diagnostic tool for model fitting. If, as a function of the threshold, it is close to a straight line, it indicates a possible good GP fitting. This is the case for the present data. More advanced tests for model fitting can also be employed and given the equivalence between equations (1) and (9), tests mentioned before can be applied.

Proceeding with model fitting, in Figure 2 are estimates of the EV index, as a function of the number of upper order statistics used in the estimation (above denoted by k). We illustrate the three estimators: moment [13], Pickands [14], and probability weighted moment (PWM) [15]. A common “problem” with these estimators and with the POT approach, in general, is the effect of the choice of the threshold on the results. This can be seen in

Figure 2, the usual variance-bias trade-off. The estimators usually show large variance for small values of k (i.e., few sample information) and large bias for large values of k (i.e., where one might be escaping from the EV condition). Though some optimal threshold choice procedures are available (e.g. [16–18]), for a “quick guess” one usually looks for the estimate in a stable region of the curves; in Figure 2, for example, -1 may be the guess.

Having a satisfactory fit to the tail, extrapolation beyond the sample range is possible and reasonable from EV theory. For instance, high quantile estimation, which for the present data would mean the estimation of some fatigue limit that would be exceeded with some given low probability. Or, the reverse problem for some given low fatigue threshold to estimate the failure probability. The estimation of the left endpoint of the pertaining distribution could be similarly addressed; note that for the present data there is an indication of a negative EV index, which corresponds to a finite endpoint of the distribution under study; cf. [4] for more on these estimators.

Further Reading and References

Many references on the applications of EV theory in reliability are easily available. Just to mention a few, included in literature more specialized in probability and statistics: in [19] the Weibull distribution was first used in the analysis of breaking strengths of metals; in [20] are inferences based on GP distributions on the sizes of large inclusions in bulks of steel; the book [21] contains a number of references on applications in structural engineering, hydraulics engineering, material strength, fatigue strength, electrical strength of materials, etc. More of a theoretical nature are: Galambos [22] with motivation of applications to strength of materials and failure of equipments; Harris [23] to sequential system lifetimes; Schuller [24] to structural engineering; Taylor [25] with an extension of the Weibull model in fitting tensile strength data; Coles and Tawn [26] with an application of multivariate extremes to structural design.

Extremely Low Frequency Electric and Magnetic Fields

Exposure

Power-frequency electric and magnetic fields (EMFs) occupy the extremely low frequency (ELF) portion of a wider electromagnetic spectrum encompassing frequencies that range from above approximately 10^{20} Hz for γ rays at the high end of the spectrum to below power frequencies of 50–60 Hz at the low end. Between the two ends of the spectrum, in order of decreasing frequency, are X rays, ultraviolet radiation, visible light, infrared radiation, microwaves, and radio waves.

ELF EMFs are associated with all aspects of the production, transmission, and use of electricity. The fields are imperceptible and are ubiquitously present in modern societies. ELF EMFs are composed of two separate components, electric fields and magnetic fields. Electric fields are created by electric charges and are measured in volts per meter (V m^{-1}). Typical residential exposure levels are under 10 V m^{-1} . In the immediate vicinity of electric appliances exposure levels can reach as high as few hundreds of volts per meter, whereas exposure levels immediately under high-tension power lines can reach several thousand volts per meter, or several kilovolts per meter (kV m^{-1}). Magnetic fields are created by moving electric charges. The unit of measurement for magnetic fields is tesla (T). Another commonly used unit in engineering sciences is gauss (G); 1 T is equivalent to $10\,000 \text{ G}$. Environmental exposure levels are described in microtesla (μT), or 10^{-6} T . Typical residential exposure levels are around $0.1 \mu\text{T}$. In the immediate vicinity of electric appliances that are in use, fields could be as high as several hundreds of microtesla, and immediately under high-tension power lines can reach up to $20 \mu\text{T}$.

Epidemiology

Since the late 1970s, numerous epidemiologic studies have investigated possible health risks from residential and occupational exposure to EMFs. Most of

some 20 epidemiologic studies investigating childhood leukemia and ELF magnetic fields have found an association between higher than average magnetic field exposure levels and leukemia risk, although a robust biologic hypothesis that could explain this association is lacking. In 2000, two independently conducted pooled analyses of previously published studies showed a statistically significant, approximately twofold increase in childhood leukemia risk for average residential exposure levels above 0.3 or $0.4 \mu\text{T}$, compared to the lowest exposure category of $\leq 0.1 \mu\text{T}$ [1, 2]. Risk increases this small or smaller are notoriously hard to evaluate in epidemiology because it is usually difficult to achieve enough precision to distinguish a small risk from no risk. Such small effect estimates, compared to larger ones, are also more likely to result from inadvertent error, or bias, that can occur in epidemiologic studies [3]. One type of bias that often goes undetected and unmeasured is confounding, which occurs when another exposure that is present along with the exposure under study is actually responsible for observed effects; another is selection bias, which can arise in the process used to select or enroll study participants [4]. Given the small associations observed in studies of magnetic fields and childhood leukemia, a limited understanding of causal risk factors for childhood leukemia, and methodological difficulties such as exposure assessment and the potential for selection bias, a conclusive interpretation of these findings remains a challenge. The lack of a robust biophysical mechanism that would explain how environmental magnetic fields could cause cancer and a lack of support from laboratory investigations further detract from the epidemiologic findings.

Epidemiologic investigation of two health outcomes, breast cancer and cardiovascular disease, has been motivated by biologically based hypotheses. Although initial studies appeared to support these hypotheses, recent, larger, and more rigorous studies have found no effects and have failed to confirm earlier findings, suggesting that ELF magnetic fields do not play a role in the development of breast cancer or cardiovascular disease.

A number of additional health outcomes (including adult leukemia, adult and childhood brain cancer, motor neuron diseases, and reproductive outcomes) have also been investigated in epidemiologic studies. Most of these outcomes were investigated to a lesser extent than childhood leukemia and the results

are inconsistent. Most of these studies also were not based on specific biologic hypotheses and lack supportive laboratory evidence.

Risk Assessment

During the past decade, a number of national and international expert panels, including panels assembled by the US National Institute of Environmental Health Sciences (NIEHS), the International Agency for Research on Cancer (IARC), the World Health Organization (WHO) [5] have reviewed the available evidence on the potential relationship between exposure to ELF EMF and various adverse health outcomes [6, 7]. Evaluations by these expert panels generally agree that short-term, adverse cellular effects do not occur with exposures to magnetic fields below 100 μ T.

The NIEHS, IARC and WHO classified ELF magnetic fields as a “possible human carcinogen”, or a group 2B carcinogen. This classification was based both on epidemiologic evidence showing a consistent association between exposure to ELF magnetic fields and childhood leukemia and on laboratory studies in animals and cells, which do not support an association between exposure to ELF magnetic fields and cancer development. The NIEHS assessment (but not the IARC or WHO assessment) concluded that there was also sufficient epidemiologic evidence for an association between adult chronic lymphocytic leukemia and occupational exposure to ELF magnetic fields to warrant a 2B classification.

Several risk characterization attempts have indicated that the public health impact of residential magnetic fields on childhood leukemia is likely to be limited [5, 8]. Positing sensitivity and bias models for methodologic problems in the epidemiologic studies and accounting for uncertainties regarding the prevalence of field levels that may have effects suggest that, in light of the available data, both no public health impact and a large impact remain possibilities [3].

The combination of widespread exposures, established biological effects from acute, high-level exposures, and the possibility of leukemia in children from low-level, chronic exposures have made it both necessary and difficult to develop consistent public health

policies. In view of these uncertainties, it might be advisable to adopt general no- and low-cost exposure reduction measures [9].

Failure Modes and Effects Analysis

Failure mode and effects analysis (FMEA) (*see* **Human Reliability Assessment; Reliability Integrated Engineering Using Physics of Failure; Probabilistic Risk Assessment**) is a systematic safety analysis method that identifies the possible system failure modes associated with a system and evaluates the effects on the operation of the system, should the failure mode occur. The focus of the analysis is on using the analysis to improve the safety of the system design (*see* **Reliability Data**).

Engineers have always informally considered what would happen if a part of the system they were designing failed. FMEA formalizes this process, ideally considering all possible failure modes, and deriving from them the effects on the system caused by the occurrence of any failure. In order to cover all aspects of the system, the FMEA process will typically bring together a team of engineers involved in all aspects of the design of the system. Once the team has examined the consequences of all possible failure modes, they should plan actions to mitigate the risks or effects of failure, documenting the actions taken and their intended effects.

FMEA, as a formal analysis discipline, originated with the American military, and was documented in military standard 1629A [1]. The automotive industry developed the practice of FMEA further, and developed a standard for performing automotive FMEA as part of its QS-9000 quality process [2]. Although QS-9000 has now been superseded by ISO/TS16949, which merges QS-9000 with European quality standards, the requirement to perform FMEA remains a part of the process. The Society of Automotive Engineers has produced two sets of standards for performing FMEA: SAE J1739 [3] for automobile applications and ARP5580 [4] for nonautomobile applications.

Types of FMEA

The main distinction between types of FMEA is between product FMEA (*see* **No Fault Found**) and process FMEA. Product FMEA considers the design for a product and concentrates on the effect of failure

of components of the design on the overall product. Process FMEA (*see* **Reliability of Consumer Goods with “Fast Turn Around”**) focuses on the potential for mistakes in the manufacturing process, which can result in the production of faulty components or systems.

FMEA can be performed on anything from a single screw up to a full car or aircraft. It will typically be requested from component suppliers by subsystem or system suppliers and from the Tier 1 suppliers by the automobile and aircraft manufacturers. FMEA effects at the component level can be fed as failure modes into higher levels of the design, forming a hierarchy of FMEAs. The severity of a failure effect at the component level cannot always be meaningfully evaluated, as it is dependent on the use of the component. This can mean that top level system FMEA results might need to be fed down to the component manufacturers through a demand for greater reliability in a specific component of the system where it is identified as vital to the safety of the overall system.

The FMEA Process

Overview

The process of producing and acting upon an FMEA report comprises the following steps:

- identify the structure and the boundaries of the system for the purposes of this FMEA;
- convene a relevant team of experts;
- identify the possible failure modes and effects;
- decide the failure effects for each possible failure mode;
- evaluate the significance of the failure mode;
- rank the failure modes by significance;
- act to mitigate the significance of the most important failure modes;
- reevaluate the significance of those failure modes taking the new action into account.

Each of these steps is explained in greater detail in the following, using an electrical system design FMEA as an example. A more extensive example of carrying out an FMEA is given in [5].

Identify the Structure and the Boundaries of the System for the Purposes of this FMEA

Typically, a product will be broken down into a set of systems in order to make FMEA tractable. It is necessary to identify the boundaries of the system in order to make sure that all aspects of the product are covered by the FMEA activity, without unnecessary duplication. For example, in a vehicle, if every electrical system considered the fusing strategy for the vehicle, there would be a great deal of wasted effort. Typically in that case, there would be a separate analysis of the fusing strategy, and the results of that fusing analysis would be used in the individual electrical FMEAs.

The available information should be identified – for electrical system design FMEA, this would be a circuit diagram for the system plus a detailed specification for the operation of each component in the system. For a process FMEA of a mechanical component, the available information might be the specification of the component plus a process flowchart for how the component is produced. For design FMEA of a more complex system, the appropriate information might be a functional block diagram.

Convene a Team of Relevant Experts

Typically, a range of people will have to be involved in specifying and designing the system undergoing FMEA. The FMEA is best carried out by a team having all the knowledge needed to design the system in the first place. So, if the design needed the involvement of electrical engineers, computer programmers, mechanical engineers, and diagnostics experts, then the FMEA activity also needs their involvement. Given the diverse experience of the team, it is often good for the team to walk through correct operation of the system, to ensure that all members of the team have a shared, correct understanding of the system. For the process FMEA of a component, the team will need to understand the operations involved in producing the component or system (e.g., lathing and welding), as well as how it works.

Identify the Possible Failure Modes and Effects

Where there is previous experience of performing FMEA on similar systems, both the potential failure modes and the possible effects on the system will be

known to a great extent. For example, an electrical relay whose switch contacts are open when the coil has no current flowing through it and are closed when current is flowing through it, will have known failure modes. It could fail such that it is open when the current is flowing through it, or such that it is closed when no current is flowing through it. Where there are new types of components in the design, then brainstorming among the team of experts may be needed to generate all the ways in which the component could fail. For more complex systems, the lower level items might be subsystems rather than simple components such as relays, and then it is often better to think of them in functional terms rather than physical terms. For example, a voltage regulator might fail to regulate the voltage, or might regulate it to the wrong value.

Similarly, where a new type of system is being designed, then brainstorming among the experts can help identify all the possible effects of failure. It is tempting to think of the system-level effects as being produced from analyzing the effects of failure, but it is better to identify all possible system-level effects initially, since they can then be used in a consistent manner as per the following steps.

Decide the Failure Effects for Each Possible Failure Mode

When the potential failure modes are known, the team of experts can mentally simulate the behavior of the system when each failure mode has occurred, and can predict which of the identified effects will occur for that failure.

Evaluate the Criticality of the Failure Mode

The significance of the failure mode can be calculated in different ways. A common method in the automotive industry is to produce a risk priority number (RPN). RPN is calculated by multiplying three different characteristics of the failure mode: severity, detection, and occurrence, each assessed on a scale of 1–10. Severity expresses how bad the effect will be, where 1 is *no effect* and 10 is *hazardous without warning*. If all the possible effects are listed before calculating what happens in failure situations, then severity can be associated with the effect at that point, and used consistently. Detection expresses whether the present design controls will detect the

presence of potential cause of failure, and therefore the failure mode before the system is released for production, where 1 means the design controls will almost certainly detect the problem, and 10 means the design control cannot detect the problem. Occurrence expresses the likelihood that the failure mode will occur, where 1 on the scale might represent a failure rate of 1 in 1 500 000 and 10 might represent a failure rate of 1 in 2.

Rank the Failure Modes by Significance

The failure modes can be ranked by the significance of their occurrence on the system, where a high RPN would be given a high significance. In addition, all failure modes where the effect has a high severity also merit detailed attention.

Act to Mitigate the Significance of the Most Important Failure Modes

High RPNs can be brought down in several ways. The severity of the effect of a failure mode can be reduced by adding redundancy, or the occurrence can be reduced by using more reliable components, or the detection value can be reduced by adding design verification or validation actions.

Reevaluate the Significance of Those Failure Modes Taking the New Action into Account

When changes have been made to the design, the RPN for the failure mode that has been addressed can be recalculated, and a decision whether further actions are necessary can be made.

Documentation of the FMEA Process

The standard way of documenting the results of an FMEA has long been the tabular approach [1], where one row of the table gives the analysis results for one failure mode. There is a column for each of the details of the FMEA, such as failure mode name, effect description, severity, occurrence and detection values, remedial action, and recalculated values.

The results can be documented in a spreadsheet, but there are specialized programs for documenting FMEAs. Some of those tools provide useful reordering of the FMEA results, such as bringing together

all equivalent failure modes (all failure modes that cause the same effect). Other tools have a database for storing and reusing failure mode names and effect descriptions so that they can be chosen from lists rather than typed into the report.

Automation of FMEA

The production of a system design FMEA report is very repetitive, with many similar failure situations being investigated. However, it is also necessary to have enough insight into the system to detect the situations that look similar to fairly innocuous situations but have much more severe consequences – hence the need for a team of experts to derive the results.

Much of the repetitive effort can be avoided by automating the generation of effects for each failure mode [6]. This works best for domains where it is possible to compose the behavior of the whole system from a description of the components of the system, the connections between them, and their individual behavior. Electrical or hydraulic systems are good examples of domains where this can be achieved. Compositionality of simulation means that the component that has the failure mode can be replaced by a faulty version, and the faulty behavior can be generated. The simulation of the system containing the failure mode can then be compared with the correct simulation enabling generation of the effects for each failure mode. This can be used to generate RPN values automatically.

There are commercial tools available that use simulation to generate the effects caused by each failure node and assign RPNs. Where these are used, it is important that they are treated as part of a wider process, where an FMEA team still looks at the ranked failure modes and decides what action should be taken to make the design safer. One of the main benefits of FMEA is the clearer understanding that the analysis gives the FMEA team about how the product works, and without this wider context, that benefit would be lost in an automated FMEA.

Further Issues

Multiple Failures

FMEA is addressed at single-point failures, but some of the worst design flaws are caused by multiple

failures. Consideration of some of these flaws can be addressed by the FMEA team identifying common types of multiple failures – for example, a failure detection mechanism failing before the failure it is intended to detect, but, in general, it would be too tedious for an FMEA team to explore even all pairs of failures.

Automation of FMEA, where possible, can address this, and Price and Taylor describe how this has been done for the automotive electrical domain, making an exploration of many failure mode combinations both feasible and useful.

Alternatives to RPN

While RPN has proved to be a popular method of assessing failure mode significance, especially within the automotive industry, it has flaws [5]. Perhaps the worst of these flaws is that it puts equal emphasis on detection of potential problems at manufacturing time as it does for likelihood of occurrence and for severity of effect. One of the reasons for this is the automobile industry's focus on avoiding warranty costs.

Other industries put more emphasis on safe and reliable operation over an extended lifetime, and neither MIL-STD-1629A [1] nor ARP5580 [4] has the same focus on detection at the time of manufacture.

The use of RPNs originally focused on RPNs that exceeded a set level (overall RPN of 100), whereas the other ways of assessing significance have always looked at ranking the failure mode/effect pairs and concentrating on the most important ones. So MIL-STD-1629A had only four levels of severity (catastrophic, critical, marginal, and minor). It recommended either a quantitative ranking of occurrence to five levels (frequent, reasonably probable, occasional, remote, and extremely unlikely) or a quantitative approach based on known failure rates. Severity and occurrence were plotted on a criticality matrix, enabling people to concentrate on those with the highest combination of severity and likelihood of occurrence.

Whatever method is used to assign significance to failure modes, it is important that it is looked on as a ranking among the failure modes rather than as an absolute value. If the more serious problems with a design or process are always addressed when an FMEA is performed, then this can form a firm foundation for continual product or process improvement.

Contribution of FMEA to Quantitative Risk Assessment

FMEA is a qualitative risk assessment discipline. It produces a ranked list of the failures that have the most impact on the safe operation of the system being studied. However, it can be used as a basis for further quantitative risk assessment. The FMEA is often seen as giving a necessary understanding of how a system works and how it can fail. If the FMEA only considers single failures, then it does not provide sufficient information to construct a fault tree for a specific top event, but has valuable supporting information. A multiple failure FMEA [7] potentially does provide enough information to construct the fault tree (*see Systems Reliability; Imprecise Reliability*). The fault tree can then be used for quantitative risk assessment in the standard way.

Wider Application of FMEA

FMEA originated as a way of identifying the potential effects of failure on the safety of engineered systems. Besides the well-known areas of automotive and aeronautic systems, FMEA has become a required part of the development for several types of naval craft [8].

FMEA has also started to make inroads into healthcare outside the obvious area of design FMEA of medical equipment. The US Department of Veteran Affairs National Center for Patient Safety has developed a healthcare FMEA [9]. It is a process FMEA for healthcare processes, focused on ensuring patient safety, and is based on developing a process flow diagram and identifying and exploring the ways in which each process in the flow can fail. Such work might well be useful in other areas where people are carrying out critical processes.

A second innovative application of FMEA in healthcare is the use of design FMEA to assess the quality of a new hospital [10]. The structure of the design being analyzed was block diagrams at the whole hospital level. They identified safety design principles such as minimal movement for critical patients. They also identified failure modes such as shortage of nursing staff and broken elevators. The effect of failure modes for specific scenarios such as urgent moving of patients between specified departments was also identified. Further FMEA, both

process and design, was carried out at the level of designing individual rooms.

Software FMEA is perhaps the most active development area for FMEA at present. The introduction of software into a wide range of embedded systems is driving Software FMEA (SFMEA) development; however, the challenges are significant owing to the complex and varied failure modes that may be introduced within software. An ever increasing proportion of the functionality of many systems is provided by software, and even if the microprocessor hardware is considered highly reliable, reliability engineers need to understand how the software behaves in the presence of failures of the supporting hardware, such as sensors and actuators.

A related area of recent interest is the concept of performing an FMEA on the software system itself. Often the aim is to locate the generic failure modes that afflict software, such as premature termination, infinite looping, memory leaks, buffer overflow, etc. [11, 12]. Other approaches attempt to determine the functional failure modes of the system by considering the possible effects of specific input or module failures on the overall system functions. This process often involves tracing potentially faulty values through the software [13] and is extremely tedious if performed manually. The concept of analyzing software designs and code, specifically to determine the effects of hypothetical faults, requires a comprehensive and relatively abstract analysis together with sophisticated reporting capabilities. Tools to assist in performing FMEA on software are being developed, but have not reached maturity as yet.

CHRIS PRICE

Fair Value of Insurance Liabilities

Insurance represents an influential and increasingly international industry that has no official international standards for financial reporting. Indeed, the great diversity in accounting practices makes it problematic for investors and regulators to assess and compare insurance companies worldwide and with other financial institutions. The last decade saw an ongoing debate on this issue (e.g., see [1, 2]) and significant changes taking place in the accounting world, culminating in the release of a standard on insurance contracts by the International Accounting Standards Board (IASB) (see **Solvency**). Key drivers of the changes have been the integration and globalization of capital markets and the strong demand by users of financial statements for greater transparency.

The new standards are characterized by a move toward market-consistent accounting, also called *fair value accounting*. As a consequence, accounting standards for the asset side of the balance sheet have witnessed a more readily and effective implementation of fair value principles (e.g., issue in 1993 of FAS115 [3], “Accounting for Certain Investments in Debt and Equity Securities”, in the United States), putting insurers in the awkward situation of marking only one side of the balance sheet to market, thus distorting equity and earnings of the company. Steps toward fair valuation of the liability side have been more difficult, since a true market for insurance liabilities does not exist, and insurance accounting practices have always been inspired to different principles.

From the point of view of financial economics, insurance contracts are just a particular example of dividend-paying securities and their valuation should certainly be market consistent. The fact that an insurance contract is illiquid and nonstandardized poses only a methodological problem, as valuation must be performed in an incomplete market setting, rather than in the usual (and more amenable) “frictionless” framework. This perspective, relevant for pricing of insurance liabilities, is emphasized to a limited extent here (see section titled “Fair Value Measurement” **Equity-Linked Life Insurance; Insurance Pricing/Nonlife**). We notice that financial economists

have been applying market valuation to insurance contracts for quite a long time, whereas actuaries and accountants have started doing so only recently. Early examples are represented by the seminal papers [4–9] (see [10] for additional references).

Here, we find it more useful to adopt an accountant’s perspective to describe how widely accepted accounting practices are being challenged by new valuation principles. We begin by providing a brief historical background on International Accounting Standards (IASs).

International Accounting Standards

The development of IASs began in 1973, when the accountancy bodies of different countries founded the International Accounting Standards Committee (IASC). After major restructuring, the committee was reformed and renamed IASB in 2001. The board adopted all of the standards prepared by the IASC and decided to produce new standards known as *International Financial Reporting Standards (IFRS)*. In 1997, the IASB set up a Steering Committee to work on the project *Insurance Contracts*. In December 1999, an Issues Paper [11] was released, attracting comments from financial institutions, supervisory authorities, and insurance companies worldwide. This feedback formed the basis for the release of a Draft Statement of Principles [12] in 2001, which later materialized into the issue of IFRS4 [13], “Insurance contracts”. The European Union having already endorsed the development of the standard in 2001, the European market provided one of the key test areas for its implementation. The standard is currently applied to a limited extent, as there are exclusions and exemptions that temporarily apply. The final phase of the IASB’s insurance project is expected to be launched within the next few years.

A number of standards are relevant to insurance business. This article is limited in scope and will mainly focuses on IFRS4, while providing only a few comments on IAS39 [14], “financial instruments”. The attention on IFRS4 is justified by two main reasons. First, the most problematic exercise the insurance industry faces is marking to market of liabilities. Second, even if the asset side of an insurer is less problematic, as it is likely to consist of more or less liquidly tradable instruments, the very same valuation framework described for liabilities can be applied to assets. Similar considerations apply in

principle to company pension liabilities, covered by IAS19 [15], “employee benefits”.

Principles of Fair Value Accounting

Fair value accounting relies on a single *recognition* and *measurement* approach for all forms of insurance contracts, regardless of the type of risk underwritten. In this section, we describe the following key principles: insurance risk and recognition of insurance contracts; definition of insurance assets and liabilities; fair value of insurance liabilities; measurement of assets and liability through a prospective, direct approach. The implementation of the measurement process is discussed in the section titled “Fair Value Measurement”.

Recognition of Insurance Risk

Under fair value accounting, the recognition of an insurance asset or liability is based on the substance of the economic transaction rather than on its legal form. An insurance contract is defined as a contract containing significant insurance risk, where *insurance risk* (see **Asset–Liability Management for Life Insurers; Correlated Risk; Basic Concepts of Insurance**) refers to uncertainty generated by risk sources other than financial risk factors (interest rates, security prices, commodity prices, credit rating, or credit indexes, etc.) and *significant* means the ability to generate changes in the net present value of the cashflows emerging from the contract. Annuities and pensions, whole life and term assurances are all examples of insurance contracts. However, by our definition, some of the contracts written by insurers may not qualify as insurance contracts: this is the case for some financial reinsurance agreements or for unit-linked products providing a death benefit not significantly higher than the account balance at the time of death. On the other hand, the divide between insurance contracts and financial instruments may be tiny: for example, while a contract requiring payments against credit downgrades of a particular entity would be accounted for as a derivative under IAS39 [14], a contract requiring payments in case of a debtor failing to pay when due would qualify as an insurance contract. The test for insurance risk is performed on a *contract-by-contract basis*, so that risk can be present even in those cases when there is minimal risk of significant changes in the present value

of the payments for a book of contracts as a whole. Also, a contract that qualifies as insurance contract at some point in time remains an insurance contract until all rights and obligations expire or are extinguished. This is relevant for endowment contracts, where sums at risk may vary considerably over the life term of the policy.

Definition of Insurance Assets and Liabilities

A cornerstone of fair value accounting is the recognition of income under an *asset and liability measurement* approach. This means that insurance assets and liabilities are identified through prespecified criteria, and then income and expenses are expressed in terms of variations in the measurement of those assets and liabilities. This is in stark contrast with the *deferral and matching* approach traditionally employed in insurance accounting, where revenue and expenses from contracts are recognized progressively over time as services are provided. An example of the latter approach is represented by the US standard FAS60 [16], released by the US-based Financial Accounting Standard Board. FAS60 prescribes the following measurement process for long-duration nonprofit life policies. Revenue is defined as investment income and premium earned, where premium is recognized in proportion to performance under the contract. Acquisition costs are deferred and amortized in proportion to premium revenue over the life of a block of contracts. This leads to recognition of a *deferred acquisition costs* asset. Liabilities are valued using assumptions reflecting best estimates plus a margin for adverse deviation. Those assumptions, once chosen, are “locked in” unless severe adverse experience develops in the future. “Unlocking” of assumptions is allowed only if a gross premium valuation shows that premium deficiency exists, thus triggering a “loss recognition” (see [1] for examples and additional discussion). Contrary to this approach, IFRS4 defines insurance assets and liabilities as assets and liabilities arising under an insurance contract. In particular, an insurer or policyholder should recognize an insurance liability (asset) when it has contractual obligations (rights) under an insurance contract that result in a liability (asset). As a consequence, items such as deferred acquisition costs remain excluded from recognition. The same applies to *catastrophe and equalization reserves*. The latter are provisions for

infrequent but severe catastrophic losses and for random fluctuations of claim expenses around expected values in some lines of business (e.g., hail and credit). They represent unearned premiums whose deferral provides for events expected to affect an entire business cycle, rather than a single reference contract, and are therefore excluded from recognition. In the approach just described, contractual rights and obligations arising from a book of contracts are seen as components of a single net asset or liability, rather than separate assets and liabilities. As a consequence, although the recognition of insurance assets and liabilities happens on a contract-by-contract basis, their measurement is performed at book level. The measurement must account only for the contracts in force at the reporting date (*closed book approach*), as an open book approach is inconsistent with a definition of assets and liabilities based on the existence, as a result of past events, of a resource or present obligation.

Fair Value of Insurance Assets and Liabilities

Fair value is defined as the amount for which an asset could be exchanged or a liability settled between knowledgeable, willing parties in an arm's length transaction. In particular, the fair value of a liability is the amount that the enterprise would have to pay a third party at the balance sheet date to take over the liability. The definition adopted is the *fair value in exchange*, as opposed to "fair value as an asset" (i.e., the amount at which others are willing to hold the liability as an asset) and "fair value in settlement with a creditor" (i.e., the amount that the insurer would have to pay to the creditor to extinguish the liability). In particular, the definition refers to a hypothetical transaction with a party other than the policyholder. Fair value is also an *exit value*, as opposed to an "entry value", which is the premium that the insurer would charge in current market conditions if she were to issue new contracts that created the same remaining contractual rights and obligations. If a liquid market existed for insurance liabilities, there would be no problem in observing exit values. In practice, secondary markets for the transfer of books of contracts are extremely thin, and exchange prices are often not publicly available. If such prices are available, they typically include an implicit margin for cross-selling opportunities, customer lists, and for future benefits arising from renewals that are not in the closed

book. The margin is often difficult to quantify, thus making problematic even the use of observed secondary market prices. The absence of observable exit prices makes it essential to estimate the fair value of a liability as if a hypothetical transaction were to take place. The favored approach is a *prospective* and *direct* method based on the expected present value of all future cash flows generated by a book of contracts. This is consistent with financial economic theory, as will be explained in the section titled "Fair Value Measurement". Before examining the actual implementation of the approach, it is useful to emphasize the key features of a prospective direct approach as opposed to alternative approaches widely adopted in insurance markets. We start with retrospective approaches, which focus on an accumulation of past transactions between policyholders and insurers. A life office, for example, could measure the insurance liability initially on the basis of the premiums received and defer acquisition costs as an asset or as a liability reduction. The expected profit margins would impact the measurement gradually over the life of the contract, in a way that depends on the technical basis assumed and on the accounting standard followed. It is typical of these approaches to use the policyholder account or the surrender value as a basis of measurement for contracts with an explicit surrender value or an explicit account balance (e.g., contracts described as universal life, unit-linked, variable, or indexed). On the other hand, a prospective approach focuses instead on the future cash inflows and outflows from a closed book of contracts and quantifies insurance liabilities through an estimate of their net present value. Such an estimate represents a provision for unexpired risk and can be more or less than the premium already paid by the policyholder, thus giving rise (unlike in the retrospective case) to a possible net profit on initial recognition. Moving on to direct and indirect methods, the latter discount all cash flows from the book of contracts and the assets backing the book, to derive a quantity that is then subtracted from the measurement of assets, giving the value of the book as a result. Direct methods discount, instead, the cashflows arising from the book of contracts and measure liabilities on that basis. Direct and indirect methods can produce the same results, provided a consistent set of assumptions is used, but direct methods usually provide greater transparency. See [17] for concrete examples in the context of

stochastic valuation models. An example of the indirect approach is the *embedded value method* (see **Securitization/Life; Risk Attitude**) (see [18]), which measures liabilities on a supervisory basis and then recognizes an asset, the embedded value, representing the amounts that will be released from the book of contracts as experience unfolds and liabilities are paid. In particular, the embedded value is given by the sum of the shareholders' net assets backing the book and the value of the business in force at the valuation date. The value of in-force business is the present value of future profits expected to emerge on the supervisory basis from policies already written (see [18] for details). The embedded value method is not market consistent, because it includes the present value of estimated future cash flows from investments representing the insurance liability. Specifically, it attributes an amount different from the fair value to assets held, because it discounts the cash flows from those investments at a rate reflecting not only the risks associated with the business, but also the cost of capital locked in by capital requirements. An evolution of the approach, known as *market-consistent embedded value method*, resolves these issues in order to achieve consistency with fair valuation.

Fair Value Measurement

The measurement of fair value relies on an expected present value approach that incorporates adjustments for uncertainty reflecting the risk preferences of market participants in a hypothetical secondary market transaction. The key ingredients to the recipe are the timing and amount of the cashflows generated by a book of contracts, and the margins for risk.

Amount and Timing of Cashflows

IFRS4 favors an explicit approach to adjustments for risk, i.e., an approach based on adding market-consistent margins on top of realistic estimates of liabilities. We therefore focus first on a realistic analysis of insurance cashflows, leaving considerations on risk adjustments for the next section. The fair valuation exercise encompasses all future pre-income tax cash flows arising from the contractual rights and obligations associated with a closed book of insurance contracts. These include future benefits and premium receipts under existing contracts,

claim handling expenses, policy administration and maintenance costs, acquisition costs, etc. Consistent with our definition of assets and liabilities, the following must be excluded among, others: cashflows arising from future business, payments to and from reinsurers (an appropriate insurance asset should, instead, be recognized), regulatory requirements, and cost of capital. Two main classes of assumptions are employed for the measurement of insurance cashflows: market assumptions, such as interest rates, for which transactions in the capital markets provide easier estimation; nonmarket assumptions, such as lapse and mortality rates or claim severities. Market assumptions should be consistent with current market prices and other market-implied data, while nonmarket assumptions must be consistent with industry assumptions. Capital markets are of course the main source of market assumptions. If a suitable replicating portfolio (see **Insurance Pricing/Nonlife; Solvency**) (i.e., an asset portfolio closely matching the insurer's obligations) can be constructed, then the market value of the portfolio would immediately provide a close proxy for the fair value of an insurance liability. Sources of nonmarket assumptions are data available to individual insurers (claims already reported by policyholders, historical data on insurers' experience), industry data, and recent exit prices observed in secondary markets. Two other markets that can provide useful information are primary markets and reinsurance markets. Primary markets for the issuance of direct insurance contracts provide information about the current pricing of risk, but can only partially reflect prices paid in wholesale markets. Reinsurance markets may provide an indication of prices that would prevail in secondary markets, but have considerable limitations: they are not generally true exit prices, as most reinsurance contracts do not extinguish the cedant's contractual obligations under the direct contract, and they may include a margin for intangible items.

Adjustments for Risk and Uncertainty

As fair value measurement is performed at book level, the definition of *book of contracts* (see **Alternative Risk Transfer**) can have significant impact on the degree of risk attached to a liability, because of pooling (several homogeneous risks pooled together) and diversification (several uncorrelated risks pooled together) effects. IFRS4 states that measurement

of insurance contracts should focus on books of contracts subject to substantially the same risks, and should reflect all benefits of diversification and correlation within those books. As a consequence, while the fair value of a book of contracts is likely to be lower than what would be obtained by considering individual contracts before aggregation, at the same time a limit is imposed to risk offsetting between different exposures. As an example, term assurances and annuities cannot be included in the same book, as opposed to current practice in some countries.

According to financial economics, there are three main methods, all theoretically correct, for implementing the expected present value approach to value a set of risky future cash flows. The first approach is the traditional discounted cash flow approach: it employs physical (real-world) probabilities to determine the expected payoffs, and discounts them at the risk-free rate plus a risk premium reflecting the riskiness of the cashflows as perceived from market participants. A second approach is risk-neutral valuation (see **Equity-Linked Life Insurance; Options and Guarantees in Life Insurance; Premium Calculation and Insurance Pricing; Volatility Smile**), where risk aversion is introduced in the probabilities and discounting is performed at the risk-free rate. Risk-neutral probabilities replace physical ones to reflect the weight that risk-averse investors would place on uncertain outcomes in a world where the expected return on any security is the risk-free rate. Finally, a third approach adjusts the cash flows directly to their certainty equivalent levels, and then discounts their realistic expected values at the risk-free rate. Here, risk aversion is introduced by specifying a utility function acting directly on the cashflows. Although the insurance industry seems to prefer an approach based on explicit adjustments (so-called market value margins) to realistic estimates of the liabilities, any of the previous methodologies should produce the same results if applied consistently. In particular, the probability adjustments introduced in the second approach would translate into proper risk-adjusted discount rates in the first approach or cashflow adjustments in the third approach. We note that many insurance contracts present complex payoff structures that require an integrated treatment of financial and insurance risks; in this situation, risk-neutral valuation is the method most fruitfully employed (see **Pricing of Life**

Insurance Liabilities; Equity-Linked Life Insurance; Options and Guarantees in Life Insurance).

Conclusion

The debate on implementation of fair value accounting is a lively area of research. The IASB's project agenda is publicly available and gives an idea of the number of issues still being debated. We have not touched upon several interesting topics, such as fair valuation of life contracts with discretionary participating features, which are subject of considerable attention by accountants, actuaries, regulators, and academics. We refer the reader to the IASB's website or to the volumes [19] and [20] for additional information on these and other matters.

Fate and Transport Models

Fate and transport models are tools used to describe how chemicals spread in the environment (*see **Statistics for Environmental Toxicity; Environmental Risk Assessment of Water Pollution***). They consist of a mathematical representation of the processes a chemical undergoes when it is released, and particularly

1. how a chemical is partitioned between different physical phases;
2. which transfer mechanisms drive it in the movement between different environmental media (air, water, soil, sediments, vegetation, biological material, etc.);
3. how a chemical reacts/is degraded within each medium;
4. how a chemical is transported within each medium.

The first point is normally dealt with standard thermodynamics equations of equilibrium partitioning. The second point involves the description of transfer mechanisms, such as absorption, volatilization, and deposition through settling particles (e.g., atmospheric particulate, suspended sediments in water).

The third point requires a representation of chemical reactions. In addition, sometimes it may be necessary to study different chemical species simultaneously. This implies the use of multispecies fate and transport models that describe not just one chemical, but also its reaction products.

The fourth point relates to the processes of diffusion, dispersion, and advection, which are in essence fluid-dynamics processes. These processes occur mainly within air and water, or the air and water phases in soil.

Phase Partitioning

In general, the total mass of chemical in a specific environmental medium is subdivided (partitioned) between the n different phases of the medium (usually including solid, liquid, gas, biological material) as

$$M = \sum_{i=1}^n C_i V_i = V \sum_{i=1}^n C_i \phi_i \quad (1)$$

where C_i is the concentration of chemical in phase i ($[M][L]^{-3}$) and V_i is the volume occupied by each phase in the medium ($[L]^3$). $V = \sum_{i=1}^n V_i$ is the total volume of the medium, and ϕ_i is the fraction of volume occupied by phase i [—]. Usually, concentration in solid/biological material is expressed in terms of mass of chemical per mass of material (massic concentration C_{Mi}). In this case, $C_{Mi} = C_i / \rho_i$, where ρ_i is the mass of material in the unit volume of medium ($[M][L]^{-3}$).

Usually, partitioning is considered in environmental modeling among the following phases for each medium:

1. air partitioning (assuming the fraction of volume V occupied by aerosol is negligible) between air and aerosol:

$$M = V(C_g + C_{Ms}TSP) \quad (2)$$

2. surface water partitioning (assuming the fraction of volume V occupied by suspended sediments and biological material is negligible) among water, suspended sediments, and biological material (e.g., fish, algae...):

$$M = V(C_l + C_{Ms}TSP + C_{Mb}BIO) \quad (3)$$

3. soil/aquifers – partitioning between soil air, soil water, and the solid matrix:

$$M = V(\theta C_l + (1 - \phi)C_{Ms}\rho_s + (\phi - \theta)C_g) \quad (4)$$

In the above equations, the symbols have the meaning listed hereafter:

C_g : concentration in gas phase $[M][L]^{-3}$

C_l : concentration in liquid phase $[M][L]^{-3}$

C_{Ms} : massic concentration in solid phase $[M][M]^{-1}$

C_{Mb} : massic concentration in biological material $[M][M]^{-1}$

TSP: concentration of particles in air (aerosol) or surface water (suspended sediments) $[M][L]^{-3}$

BIO: concentration of biological material $[M][L]^{-3}$

ϕ : volume fraction of soil which is not solid, or soil porosity [—]

θ : volume fraction of soil which is occupied by water, or soil moisture content [—]

ρ_s : soil solid density $[M][L]^{-3}$.

For a more thorough discussion, the reader is referred to [1].

Often, we assume that C_g , C_{Ms} , C_{Mb} , and C_l are all related among each other independent on time, so that $C_g = f(C_l)$, $C_{Ms} = f'(C_l)$ etc., where f , f' , $\dots$, are appropriate functions. This assumption is called the *equilibrium partitioning* assumption. The most simple function that can be adopted for concentrations in two phases a, b, is in the form $C_a = kC_b$ (linear equilibrium partitioning) where k is a constant called the *partitioning coefficient*. The partitioning coefficient can be dimensionless if concentration in both phases is in the same dimensions; the solid–liquid partitioning is often expressed in $[L]^3[M]^{-1}$ as a ratio of massic and volumetric concentrations. Partitioning functions can be nonlinear; particularly common are the Langmuir and Freundlich equations [2]. The solid–liquid partitioning coefficient is also called *distribution coefficient* K_d , and is normally expressed as a product of the organic carbon content of the solid, and the octanol–water equilibrium partitioning coefficient K_{ow} , a physicochemical property of substances that can be estimated experimentally. The gas–liquid partitioning coefficient is also called (nondimensional) *Henry's constant* K_{aw} and represents a physicochemical property of substances as well. K_{ow} and K_{aw} can be strongly dependent on temperature.

The equilibrium assumption implies that concentration in all phases is determined once concentration in a single phase is known.

Transfer to Other Media

Transfer to other media can occur in the form of diffusive or advective process. The first category includes in particular absorption of gases at, and volatilization from, one surface, which can be liquid or solid.

Advective processes include transport of substances through the removal of particles, or as dissolved in moving fluids.

Such processes can be described using the following general mathematical representation:

$$Q_{a,b} = A \sum_{i=1}^n C_i u_{i,(a,b)} \quad (5)$$

where $Q_{a,b}$ is the total flux of a substance from medium a to medium b, C_i is the concentration in

each of the n phases of medium a $[M][L]^{-3}$, and $u_{i,(a,b)}$ is the transfer rate in that phase from medium a to medium b $[L][T]^{-1}$. A represents the surface area of the interface between media a and b $[L]^2$.

In the case of air, the phases involved are (a) gas, (b) aerosol particles, and (c) raindrops. Snowflakes can be also included; they are normally described in an intermediate way between raindrops and aerosol particles. For simplicity, we neglect this additional phase here, with no loss of generality in the discussion. Concentration in the gas phase, in raindrops, and on aerosol particles are related to each other under equilibrium assumptions. Media a and b are identified as air, and either soil, water surfaces or canopies. The transfer rates represent the following:

- $u_{1(a,\text{surf})}$: gas absorption velocity at the air–surface interface;
- $u_{2(a,\text{surf})}$: aerosol (dry) deposition velocity;
- $u_{3(a,\text{surf})}$: wet deposition velocity.

Wet deposition is the process by which raindrops deposit to surfaces both gaseous substances by absorption, and particles (and consequently particle-attached chemicals) by scavenging. There are several ways to parameterize the above listed transfer rates; usually, gas absorption is given as a function of wind speed over the surface and the humidity of the surface itself, dry deposition is a function of turbulence and atmospheric stability, and wet deposition is a function of rainfall intensity and the duration of interstorm periods. Also, the type of land use strongly affects the transfer through dry deposition and gas absorption. The reader is referred to the literature for further details [3, 4].

In the case of surface water, the phases involved are (a) suspended solids and (b) the water phase. The transfer rates represent the following:

- $u_{1(w,\text{sed})}$: deposition velocity of particles due to gravitational and turbulent settling, toward the water body bottom sediments;
- $u_{2(w,a)}$: velocity of volatilization to the atmosphere.

Deposition velocity of particles can be estimated using Stokes' law under laminar conditions and with semiempirical formulas under turbulent conditions [5]. The velocity of volatilization is normally assumed equal to the velocity of gas absorption and

the net exchange between air and water is driven by the relative concentrations [3].

In the case of soil, the phases involved are (a) soil solids, (b) air, and (c) water in the soil pores. The transfer rates represent the following:

- $u_{1(s, \text{sed})}$: volumetric erosion rate;
- $u_{2(s, w)}$: runoff rate + rate of percolation to the water table;
- $u_{3(s, a)}$: velocity of volatilization to the atmosphere.

The erosion rate is the amount of soil solids lost per unit time and surface. The runoff/percolation rates are the amount of water leaving the soil per unit time and surface. The velocity of volatilization is evaluated as in the case of water; normally it is assumed that volatilization occurs in parallel between soil air and air, and between soil water and air. The diffusion velocities inside the soil pores are assumed to be lower than the corresponding ones in free air or water [6].

Reactions/Degradation

Reaction kinetics can be extremely complex, but up to now it has been common practice to use very simple kinetic models, such as, in most cases, linear models. In some environmental fate and transport models, other types of kinetics are also used [7]. In general, a simplified linear representation of nonlinear, or otherwise complex phenomena is acceptable when the variation of the quantities involved is limited around certain typical values. The use of linear models is reasonable insofar as the errors introduced by this simplification are small compared with the other sources of uncertainty or errors. This is often the case in environmental modeling, which involves many parameters difficult to determine, and even many processes difficult to describe in equations. According to the linear model, the flux of substance that is degraded $[M][T]^{-1}$ is

$$Q_{\text{deg}} = V \sum_{i=1}^n k_i \phi_i C_i \quad (6)$$

where k_i is the degradation rate of the substance in phase i $[T]^{-1}$, C_i its concentration $[M][L]^{-3}$, and V the bulk volume of the medium $[L]^3$. The degradation rates are either determined experimentally, or estimated from similar properties such as reaction

rate with a known standard. Further details can be found in [3]. Usually it is recognized that the degradation rates depend strongly on temperature [3]. The reaction rates of substances in the environment are a highly uncertain parameter in most fate and transport models; often an “overall” degradation rate is preferred to phase-specific ones as in equation (6), in that it is considered as a model parameter to be calibrated.

Transport within an Environmental Medium without Reactions and Generalization to Simple Multiphase Situations with Reactions

The transport of a conserved substance within a medium (i.e., a substance not subject to degradation nor to transfer to other media) is due to two types of phenomena: advection and diffusion (called *dispersion* whenever it occurs in turbulent media). Diffusion (dispersion) can be described as a process by which a chemical tends to move from regions at higher concentration, to regions at lower concentration (Fick’s law) [8]. Accordingly, the components of the diffusion (dispersion) flux vector of a substance at point (x, y, z) $[M][T]^{-1}$ is given by

$$\overline{Q}_{\text{diff}} = \begin{bmatrix} Q_{\text{diff}, x} \\ Q_{\text{diff}, y} \\ Q_{\text{diff}, z} \end{bmatrix} = \overline{\overline{D}} \times \text{grad } C \quad (7)$$

where $\overline{\overline{D}}$ is called *diffusion (dispersion) coefficients matrix* ($[L]^2[T]^{-1}$). An element (I, j) of this matrix represents the diffusion (dispersion) flux occurring in direction i for a unit concentration gradient in direction j . Often, it is assumed to be a diagonal matrix.

Advection is a process by which a chemical is transported along the flow pathways of a motion field $v(x, y, z)$, i.e., a vector of velocities along directions (x, y, z) defined for each point in space. The advection flux vector of a substance at point (x, y, z) $[M][T]^{-1}$ is given by

$$\overline{Q}_{\text{adv}} = C \overline{v} \quad (8)$$

where v is the vector of velocity of the fluid. The mass balance equation of a conservative substance for a given reference volume of an environmental medium (e.g., air, soil, water) can be written as:

$$\frac{\partial C}{\partial t} = \text{Emission} - \text{dispersion} - \text{advection} \quad (9)$$

where the dispersion and advection terms are mathematically derived as the divergence of Q_{diff} and Q_{adv} through appropriate analytical steps [9], and emission term represents the input of substance from outside and is called sometimes *source-sink term*. In this way we obtain the advection–dispersion equation (ADE):

$$\frac{\partial C}{\partial t} = \text{Emission} - v \times \text{grad } C - \text{div} (\bar{D} \times \text{grad } C) \quad (10)$$

In the above notation, $\times$ represents the matrix product of vectors, div the divergence operator and grad the gradient operator. The ADE is a very general tool that describes the mass balance of a single substance in a single medium and phase. It can be solved analytically or numerically once initial and boundary conditions are set. Boundary conditions represent, in particular, the specific conditions of mass exchange between a medium, where the ADE is solved, and its external interfaces. Analytical solutions exist for very simple cases such as parallel flow, zero-velocity (dispersion only), and simple boundary conditions [10]. Methods to solve this equation numerically include finite elements, finite differences and the method of characteristics (MOC). Some methods of solution of the ADE require to represent it in Lagrangian form, i.e., through the substantial (Lagrangian) derivative $\frac{d\bullet}{dt} = \frac{\partial\bullet}{\partial t} + v \times \text{grad}(\bullet)$:

$$\frac{dC}{dt} = \text{Emission} - \text{div}(D \times \text{grad } C) \quad (11)$$

Additional details are provided e.g., in [11].

It is easy to generalize the ADE by including reactions in the case of a single phase. In such cases, the mass balance equation is:

$$\begin{aligned} \frac{\partial C}{\partial t} = & \text{Emission} - \text{dispersion} - \text{advection} \\ & - \text{degradation} \end{aligned} \quad (12)$$

which becomes, using a linear model for degradation,

$$\begin{aligned} \frac{\partial C}{\partial t} = & \text{Emission} - v \times \text{grad } C - \text{div} (D \text{ grad } C) \\ & - kC \end{aligned} \quad (13)$$

where k is the degradation rate. In this way, the chemical that is degraded is considered as a net loss from the system, and no description is provided about the evolution of the reaction products in the environment. The above equation is referred to as the advection–dispersion–reaction equation (ADRE).

If one assumes equilibrium between the different phases of an environmental medium, it is possible to write the ADRE to include multiple phases in a medium. Assume C is the concentration in the medium a of interest, in phase X where advection and dispersion take place. For instance, this could be the dissolved phase in water, or the gas phase in the atmosphere. Assume for simplicity linear equilibrium between phases. Concentration in each of the other phases is expressed as $C_i = \zeta_i C$, where ζ_i is the partitioning coefficient between phase i and phase X . It is clear that $\zeta_X = 1$, and the overall degradation flux is

$$Q_{\text{deg}} = V \sum_{i=1}^n k_i C_i = VC \sum_{i=1}^n k_i \zeta_i \quad (14)$$

Using the same reasoning, the removal flux from medium a toward another medium b is

$$Q_{a,b} = A \sum_{i=1}^n C_i u_{i,(a,b)} = AC \sum_{i=1}^n \zeta_i u_{i,(a,b)} \quad (15)$$

Also, the total concentration of chemical in the medium is the sum of the concentration in all phases, weighted with the volume fraction of each phase:

$$C_{\text{tot}} = \sum_{i=1}^n C_i \phi_i = C \sum_{i=1}^n \zeta_i \phi_i \quad (16)$$

The ADRE is written then with reference to the total concentration, but advection and dispersion only occur in phase X .

Under these assumptions, the ADRE can be further generalized in the following form:

$$\begin{aligned} \sum_{i=1}^n \zeta_i \phi_i \frac{\partial C}{\partial t} = & \text{Emission} - v \times \phi_X \text{ grad } C \\ & - \text{div} (\phi_X D \text{ grad } C) \\ & - C \left(\sum_{i=1}^n \phi_i k_i \zeta_i + \sum_{b=1}^m \sum_{i=1}^n \zeta_i u_{i,(a,b)} \right) \end{aligned} \quad (17)$$

where C is the concentration of substance in medium a in phase X , and m is the number of other media where the substance can be transferred from medium a . the above formulation of the ADRE is rather general and allows describing a very broad range of fate and transport problems for substances in the environment. Writing an equation of the type (17) for each medium involved in the transport process

provides a system of equations which allow predicting all concentrations simultaneously. In the following, we will provide an explicit formulation of the ADRE for specific individual media.

Fate and Transport in Soil and Aquifers

In soils and aquifers, generally one is interested in the dissolved phase of chemicals in groundwater; however, for specific problems the explicit description of air flow in soils can be required, e.g., for the design of soil remediation from volatile contaminants. We refer here to the water-dissolved concentration C for reference. Concentration in soil solids is expressed as $C_{Ms} = K_d C = f_{oc} K_{ow} C$ where f_{oc} is the fraction of organic carbon in soils; accordingly, $C_s = \rho_s C_{Ms}$. Also, concentration in soil air is $C_a = K_{aw} C$. In this case, the ADRE is written as:

$$\begin{aligned} & (\theta + (\phi - \theta)K_{aw} + (1 - \phi)\rho_s K_d) \frac{\partial C}{\partial t} \\ &= \text{Emission} - v \times \theta \text{ grad } C - \text{div } (\theta D \text{ grad } C) \\ & \quad - C(\theta k_{sw} + (\phi - \theta)K_{aw}k_{sa} + (1 - \phi)\rho_s K_d k_s \\ & \quad + u_{1,(s, \text{sed})}\rho_s K_d + u_{3,(s,a)}K_{aw}) \end{aligned} \quad (18)$$

where k_s is the degradation rate of the substance adsorbed to the soil solids, k_{sa} is the one for the substance in soil air and k_{sw} for soil water. It is worth noting that the transfer from soil/aquifer to other water bodies (e.g., deeper aquifers, surface water), represented by the term $u_{2,(s,w)}$ introduced above, is incorporated in the ADRE implicitly in the advective term, and controlled by the boundary conditions that allow solving the equation.

A special case is when soil is saturated in water ($\phi = \theta$). Such condition occurs normally in deeper layers of the soil/aquifer, so that erosion can be neglected. In this case, the ADRE is simplified to

$$\begin{aligned} & (\phi + (1 - \phi)\rho_s K_d) \frac{\partial C}{\partial t} = \text{Emission} - v \times \phi \text{ grad } C \\ & \quad - \text{div } (\phi D \text{ grad } C) \\ & \quad - C(\phi k_{sw} + (1 - \phi)\rho_s K_d k_s \\ & \quad + u_{3,(s,a)}K_{aw}) \end{aligned} \quad (19)$$

and the term $(\phi + (1 - \phi)\rho_s K_d)$, called *retardation factor*, represents the ratio of the speed of the contaminant on the speed of soil water [12]. The dispersion coefficients D are estimated on the basis

of criteria for which the reader is referred to [13]. The velocity vector is evaluated in soil and groundwater according to the Darcy law [12]:

$$v = \frac{\overline{\overline{K}} \times \text{grad } h}{\phi} \quad (20)$$

where $\overline{\overline{K}}$ is the hydraulic conductivity matrix [L] [T]⁻¹ and h is the total hydraulic head [L]. In general, K depends on soil water saturation θ and is represented through theoretical relations $K(\theta)$ [14].

In complex cases, the values of v are provided by appropriate hydrodynamic models solving the water mass balance equation [12, 15–17]. At present, many computer models exist that solve the ADRE for soil and groundwater. Among them, it's worth quoting the MT3D model for saturated soil in three dimensions, produced by the United States Environmental Protection Agency (USEPA) [18]; VS2DT for variably saturated soil in two dimensions, produced by the United States Geological Survey (USGS) [19], and SUTRA for variably saturated soil in two and three dimensions, produced by the USGS [16].

Fate and Transport in Surface Water

Following the same reasoning as in the case of soil and aquifers, but considering the only two phases present in surface water (suspended solids and the water solution), the ADRE can be written as

$$\begin{aligned} & (1 + TSP K_d) \frac{\partial C}{\partial t} = \text{Emission} - v \times \text{grad } C \\ & \quad - \text{div } (D \text{ grad } C) \\ & \quad - C(k_w + TSP K_d k_{ss}) \\ & \quad - (u_{1,(w,s)} TSP K_d \\ & \quad + u_{2,(w,a)} K_{aw}) C \end{aligned} \quad (21)$$

We refer here again to the water-dissolved concentration C for reference.

In rivers, in most practical cases flow can be regarded as one dimensional; often dispersive fluxes can be neglected ($D = 0$) as they are much smaller than advective fluxes. Moreover, if emissions are reasonably constant over a period, steady state is often reached, i.e., the time derivative in the ADRE vanishes. If these conditions are met, one obtains the so-called plug flow equation [20] which is an ordinary

differential equation of the first order. This can be written as

$$v \frac{dC}{dx} = \text{Emission} - C(k_w + TSP K_d k_{ss}) - (u_{1(w,s)} TSP K_d + u_{2(w,a)} K_{aw}) C \quad (22)$$

This equation has an analytical solution if the *emission* term can be represented in a mathematically tractable form; additional discussion can be found in [20]. A special case of interest is the one of a continuous point emission in a stream with constant velocity, settling velocity, and suspended solid concentration, with no other emission along the stream. In such case, if C_0 is the concentration in the stream at the emission point, the spatial distribution of concentration along the stream is

$$C = C_0 \exp \left(-\frac{x}{v} \left(k_w + TSP K_d k_{ss} + u_{1(w,s)} TSP K_d + u_{2(w,a)} K_{aw} \right) \right) \quad (23)$$

This case is of particular interest as it represents well the fate of a chemical emitted from e.g., an industrial outflow or a waste water treatment plant, and it allows a screening level assessment of the expected pollution in the receiving water.

Dispersion coefficients in surface water can be estimated either by empirical methods [21] or using more theoretical fluid-dynamics methods based e.g., on the deformation velocity of the fluid in motion [22]. Advection velocity is normally computed using semiempirical hydraulic functions such as Manning's formula:

$$v = \frac{1}{n} R^{\frac{2}{3}} \sqrt{J} \quad (24)$$

where R is the hydraulic radius (ratio between flow cross section area and cross section wetted perimeter [L]), n is an empirical roughness coefficient $[T][L]^{1/3}$, and J is the gradient of the total hydraulic head. For complex flow conditions, such as irregular geometry of the water body, hydraulic structures, the presence of wind at the water surface, tides or water waves at the boundary of the water body, the computation of velocities need to be described using an appropriate hydraulic model [22–24].

Some models commonly used to solve the ADRE for surface water are QUAL2K [25] for one-dimensional flow, SWAT [26] for catchment scale processes, WASP [27] for two dimensional flow; a

rather general model used for coastal waters and complex two dimensional problems is COHERENS [24].

Fate and Transport in the Atmosphere

In the case of the atmosphere (*see Air Pollution Risk*), the chemical is partitioned between a gas phase and a particle phase (aerosol or particulate matter, with concentration $TSP [M][L]^{-3}$). We refer here to the gas-phase concentration C for reference.

We call $K_{pm,a}$ the linear–equilibrium–partitioning coefficient. Usually this coefficient is expressed as a function of the substance properties K_{aw} and K_{ow} (e.g., [1]). Also, raindrops (and snow flakes) act by absorbing chemicals in gas phase and scavenging aerosol. The concentration of chemical in raindrops coming from the gas phase during rainfall is usually evaluated assuming equilibrium between rainwater and the gas phase itself, and is therefore $C_{raindrop, gas} = C K_{aw}^{-1}$. The concentration in raindrops coming from the aerosol during rainfall is evaluated through an empirical “washout factor” W_{pm} (nondimensional), so that $C_{raindrop, pm} = C W_{pm} TSP K_{pm,a}$. Under these assumptions, the ADRE becomes:

$$\begin{aligned} (1 + TSP K_{pm,a}) \frac{\partial C}{\partial t} &= \text{Emission} - v \times \text{grad } C - \text{div } (D \text{ grad } C) \\ &- \left(k_a + TSP K_d k_{pm} + u_{1(a,surf)} + u_{2(a,surf)} TSP K_{pm,a} \right. \\ &\left. + \left(\frac{1}{K_{aw}} + W_{pm} TSP K_{pm,a} \right) u_{3(a,surf)} \right) C \end{aligned} \quad (25)$$

where k_a is the degradation rate in the gas phase, and k_{pm} is the one in the aerosol phase. This equation is usually solved in three dimensions with numerical methods from appropriate initial and boundary conditions. Advection velocity represents here wind speed, and is usually provided by atmospheric circulation models. Dispersion coefficients are usually estimated theoretically from air fluid–dynamic considerations [21]. Although recent developments in computing power support the use of complex three-dimensional models also for relatively simple, local scale problems, a practical solution to the ADRE for local applications is still the one provided by the so-called Gaussian models. This class of models grounds on an analytical, steady-state solution of the ADE

(i.e., neglecting the reaction and removal terms) that corresponds to constant emission, with emission rate Q [M][T]⁻¹, in a wind field of constant direction and intensity. If x is the abscissa originating from the emission point and directed along the wind, y its perpendicular in the horizontal, and z in the vertical plane, the analytical solution is:

$$C(x, y, z) = \frac{Q}{4\pi x \sqrt{D_y D_z}} \exp\left(-\frac{vy^2}{4D_y}\right) \times \left(\exp\left(-\frac{v(z+z_s)^2}{4D_z}\right) + \exp\left(-\frac{v(z-z_s)^2}{4D_z}\right) \right) \quad (26)$$

where z_s represents the elevation of the emission point, v the wind speed, D_y and D_z the dispersion coefficients in y and z directions. This base solution describes a spatial distribution of concentrations in the form of a plume, and can be generalized to include many additional effects, through empirical or semiempirical corrections. Commonly, effects included in Gaussian models are the variability of winds (through statistical treatment of the joint-frequency function of wind direction and intensity, or wind rose, for a specific site); reactions, atmospheric deposition; building downwash (modified turbulence due to aerodynamic obstacles); effects of complex terrain such as mountains. A model commonly used in the past to treat these features is ISC3 from USEPA [28]. ISC3 also deals with areal and linear emissions, while a specific Gaussian model used for linear emissions from road traffic is CALINE from the State of California EPA [29]. Also, modifications have been proposed to cope with puff-type emissions [30] and for periods of no-wind (dispersion only) [31]. Another similar model of wide application is ADMS [32].

When using Gaussian plume models, dispersion coefficients are often represented as a simple function of x and atmospheric stability conditions [33].

Models of higher complexity, but widely used at present, include CAMx [34] and AERMOD [35]. These models are suitable for studies at regional to local scale. For wider domains such as a continent, a hemisphere or the globe, models such as TM5 [36] and MM5 [37] are better suited as they are directly linkable to general circulation models (GCMs) of the atmosphere and allow simulating transport in a fully three-dimensional atmospheric domain.

Box Models, Multimedia, and Multispecies Fate and Transport

The ADE and ADRE described above allow a detailed simulation in space and time of the fate and transport of chemicals in the environment. However, solving these equations can be demanding both in terms of computational burden, and for what concerns input data acquisition. This becomes particularly problematic when simulating at the same time more environmental media, and/or more chemical species. In such circumstances, it is common practice to describe the environment in the form of a set of well-mixed (uniform concentration) compartments, often referred to as *continuous stirred tank reactors* (CSTR), or simply *boxes*, hence the terming *box models* when using this approach. Each CSTR represents one specific phase in an environmental medium. The mass balance for a chemical in a CSTR of volume V is given by the following equation:

$$V \frac{dC}{dt} = E + \sum_{i=1}^n Q_{in}^i C_{in}^i - Q_{out} C - KC \quad (27)$$

where E is a direct mass flow rate of chemical into the CSTR, K is a term that lumps together all degradation and removal processes from the CSTR, Q_{in}^i is each of the n volumetric flow rates of the phase entering the CSTR from outside, C_{in}^i its concentration of chemical, Q_{out} is the volumetric flow rate exiting the CSTR, and C is the concentration of chemical in the CSTR. The above equation is an ordinary differential one and has an analytical solution for each period for which the terms $(E + \sum_{i=1}^n Q_{in}^i C_{in}^i)$, Q_{out} and K can be regarded as constant. Let us consider now two boxes exchanging the chemical. Let us use the subscripts 1 and 2 for the respective quantities. It is then possible to write a system of two equations as:

$$\begin{aligned} V_1 \frac{dC_1}{dt} &= E_1 + Q_{21} C_2 - Q_{out,1} C_1 - K_1 C_1 \\ V_2 \frac{dC_2}{dt} &= E_2 + Q_{12} C_1 - Q_{out,2} C_2 - K_2 C_2 \end{aligned} \quad (28)$$

where Q_{21} represents the volumetric flow rate from box 2 to box 1, Q_{12} *vice versa*. The system can be generalized to m boxes and written in matrix form as:

$$\frac{d\bar{C}}{dt} = \bar{E} - \bar{K} \bar{C} \quad (29)$$

where $\bar{C}$ is the vector ($m \times 1$) of concentrations in each box, $\bar{E}$ is the corresponding vector of emissions, $\bar{K}$ is the rate matrix ($m \times m$) representing at the generic off-diagonal position (i, j) the total rate of transfer from box i to box j , and at the diagonal position (i, i) the total removal rate of chemical at box i toward all other boxes and out of the system in form of degradation.

The scheme can be applied to all the following cases, or a combination of them:

1. a single phase: different boxes correspond to different locations in space (for instance, the water phase of a lake can be subdivided into subregions to describe chemical concentrations arising from emissions at different points);
2. more phases: different boxes correspond to different phases (for instance, we can use a box for each phase to describe the exchanges along a column of air, water, and sediment);
3. a single phase and more chemical species (for instance, we can describe organic nitrogen, ammonia, nitrogen dioxide, and nitric nitrogen in a lake where denitrification occurs in the water phase). In such case, the transfer rates represent rates of reaction from/to each chemical species.

This reasoning enables both multimedia and multispecies modeling through systems of equations all similar to the above. Instead of each individual phase one might model together an environmental medium including more phases, under the equilibrium assumption. In this case, the concentration in a medium can be a total concentration, or a concentration in a specific phase, the other phases being automatically determined by the equilibrium assumptions. A thorough discussion of box models can be found in [1].

Fault Detection and Diagnosis

The detection and diagnosis of malfunctions in technical systems is of great practical significance [1]. Such systems include production equipment (such as chemical plants, steel mills, paper mills, and power stations), transportation vehicles (ships, airplanes, and automobiles), and household appliances (washing machines and air conditioners). In any of these systems, malfunctions of system components may lead to damage of the equipment itself, degradation of its function or product, jeopardy of its mission, and hazard to human life. While the need to detect and diagnose malfunctions is as old as the construction of such systems, advanced fault detection has been made possible only by the proliferation of the computer. Fault detection and diagnosis actually mean a scheme in which a computer monitors the technical equipment to signal any malfunction and determine the components responsible for it. The detection and diagnosis of the fault may be followed by automatic actions enabling the fault to be corrected, such that the system may operate successfully even under the particular faulty condition, or it may lead to the emergency shutdown of the system.

Diagnostic Concepts

Fault detection and diagnosis apply to both the basic technical equipment and the actuators and sensors attached to it. In the case of a chemical plant, for example, the former includes the reactors, distillation columns, heat exchangers, compressors, storage tanks, and piping. Typical faults are leaks, plugs, surface fouling, and broken moving parts. The actuators are mostly valves, together with their driving devices (electric motors and hydraulic or pneumatic drives). The sensors are devices measuring the different physical variables in the plant (such as thermocouples, pressure diaphragms, and flowmeters). Actuator and sensor fault detection is very important because these devices are quite prone to faults [1, 2].

The on-line or real-time detection and diagnosis of faults mean that the equipment is constantly monitored during its regular operation by a permanently connected computer, and any discrepancy is signaled

almost immediately. On-line monitoring is very important for early detection of any component malfunction before it can lead to more substantial equipment failure. In contrast, off-line diagnosis involves the monitoring of the system by a special, temporarily attached device, under special conditions (for example, car diagnostics at a service station).

The diagnostic activity may be broken down into several logical stages. Fault detection is the indication of something going wrong in the system. Fault isolation is the determination of the fault location (the component which malfunctions), while fault identification is the estimation of its size. On-line systems usually contain the detection and isolation stages; in off-line systems, detection may be superfluous. Fault identification is usually less important than the other two stages.

Fault detection and isolation can never be performed with absolute certainty, because of circumstances such as noise, disturbances, and model errors (see **Subjective Expected Utility**). There is always a trade-off between false alarms and missed detections, the proper balance depending on the particular application. In professionally supervised large plants, false alarms are better tolerated and missed detections may be more critical, while in consumer equipment (including cars) the situation may be the opposite [1, 2].

Approaches

A number of different approaches to fault detection and diagnosis may be used, individually or in combination.

Limit Checking

In this approach, which is the most widely used, system variables are monitored and compared to preset limits. This technique is simple and appealing, but it has several drawbacks. The monitored variables are system outputs that depend on the inputs; to make allowance for the variations of the latter, the limits often need to be chosen conservatively. Furthermore, a single-component fault may cause many variables to exceed their limits, so it may be extremely difficult to determine the source. Monitoring the trends of system variables may be more informative, but it also suffers from the same limitations as limit checking (see **Decision Modeling**) [2].

Special/Multiple Sensors

Special sensors may be applied to perform the limit-checking function (for example, as temperature or pressure limit sensors) or to monitor some fault-sensitive variable (such as vibration or sound). Such sensors are employed mostly in noncomputerized systems. *Multiple sensors* may be applied to measure the same system variable, providing physical redundancy. If two sensors disagree, at least one of them is faulty. A third sensor is needed to isolate the faulty component (and select the accepted measurement value) by “majority vote”. Multiple sensors may be expensive, and they provide no information about actuator and plant faults [2].

Frequency Analysis

This procedure, in which the Fourier transforms of system variables are determined, may supply useful information about fault conditions. The healthy plant usually has a characteristic spectrum, which will change when faults are present. Particular faults may have their own typical signature (peaks at specific frequencies) in the spectrum (*see Non- and Semi-parametric Models and Inference for Reliability Systems*) [2].

Fault-Tree Analysis

Fault trees are the graphic representations of the cause–effect relations in the system. On the top of the tree there is an undesirable or catastrophic system event (“top event”), with the possible causes underneath (“intermediate events”) down to component failures or other elementary events (“basic events”) that are the possible root causes of the top event. The logic relationships from bottom-up are represented by AND and OR (or more complex) logic gates. Fault trees can be used in system design to evaluate the potential risks associated with various component failures under different design variants (bottom-up analysis). In a fault diagnosis framework, the tree is utilized top down; once the top event is observed, the potential causes are analyzed by following the logic paths backwards; (see example below (*see Influence Diagrams*) [3]).

Parameter Estimation

This procedure utilizes a mathematical model of the monitored system. The parameters of the model

are estimated from input and output measurements in a fault-free reference situation. Repeated new estimates are then obtained on-line in the normal course of system operation. Deviations from the reference parameters signify changes in the plant, and a potential fault. The faulty component location may be isolated by computing the new physical plant parameters and comparing them with those from the model [4].

Consistency Checking

This is another way of utilizing the mathematical system model. The idea is to check if the observed plant outputs are consistent with the outputs predicted by the model. Discrepancies indicate a deviation between the model and the plant (parametric faults) or the presence of unobserved variables (additive faults). This testing concept is also called *analytical redundancy* since the model equations are used in a similar way as multiple sensors under the physical redundancy concept described above [4, 5].

As a preparation for fault monitoring by analytical redundancy methods, a mathematical model of the plant needs to be established. This may be done from “first principles” relying on the theoretical understanding of the plant’s operation, or by systems identification using experimental data from a fault-free plant.

The actual implementation of fault monitoring usually consists of two stages (Figure 1). The first is residual generation; residuals are mathematical quantities expressing the discrepancy between the actual plant behavior and the one expected on the

Figure 1 Model-based fault detection and diagnosis

basis of the model. Residuals are nominally zero; they become nonzero by the occurrence of faults. The second stage is residual evaluation and decision making; the residuals are subjected to threshold tests and logic analysis.

The detection of faults is complicated by the presence of disturbances and noise; these affect the plant outputs, just as faults do, and may cause the residuals to become nonzero, leading to false alarms. With model-based methods, model errors are another potential source of false alarms. Designing residual generators that are (at least somewhat) robust with respect to noise, disturbances, and model errors is a fundamental issue in technical diagnostics.

Fault isolation requires specially manipulated sets of residuals. In the most frequently used approach, residuals are arranged so that each one is sensitive to a specific subset of faults ("structured residuals"). Then, in response to a particular fault, only a fault-specific subset of residuals triggers its test, leading to binary "fault codes" (see example below).

Principal Component Analysis (PCA)

In this approach, empirical data (input and output measurements) is collected from the plant. The eigenstructure analysis of the data covariance matrix yields a statistical model of the system; the eigenvectors point at the "principal directions" of the relationships in the data while the eigenvalues indicate the data variance in the principal directions. This method is successfully used in the monitoring of large systems; by revealing linear relations among the variables the dimensionality of the model is significantly reduced. Faults may be detected by relating plant observations to the normal spread of the data; outliers indicate abnormal system situations. Residuals may also be generated from the principal component model, allowing the utilization of analytical redundancy methods in this framework (see **Copulas and Other Measures of Dependency**) [6].

Example of Fault-Tree Analysis – Simple Electrical Circuit

The schematic of a simple electrical circuit in which a light is operated by a pair of three-way switches is shown in Figure 2. (Such circuits are used e.g., in

Figure 2 Simple electrical circuit: a lamp operated by a pair of three-way switches [Reproduced from [1]. © McGraw-Hill, 2006.]

long hallways.) Figure 3 shows the detailed fault tree of the circuit. The tree goes down to subcomponents (contacts of the switches) in order to illustrate the more complex logic relations on this simple system. Note that nonfailure events (operating conditions) are also among the basic events because such conditions (the position of each switch) determine whether or not a particular failure event triggers the top event [1].

Example of Consistency Checking – Application to Automobile Engines

Traditionally, a few fundamental variables, such as coolant temperature, oil pressure, and battery voltage, have been monitored in automobile engines by using limit sensors. With the introduction of on-board microcomputers, the scope and number of variables that can be considered have been extended. Active functional testing may be applied to at least one actuator, typically the exhaust-gas recirculation valve. Model-based schemes to cover the components affecting the vehicle's emission control system are gradually introduced by manufacturers.

As an example, consider the intake manifold subsystem (Figure 4). The subsystem includes two actuators, the throttle (THR) and the exhaust-gas recirculation (EGR) valve, and two sensors, measuring the manifold absolute pressure (MAP) and mass air flow (MAF). The two outputs (MAP and MAF) depend on the two inputs (THR and EGR); their relationship may be determined empirically or by physical modeling. The two model equations are

$$\text{MAP} = f_1(\text{THR}, \text{EGR}) \quad (1)$$

$$\text{MAF} = f_2(\text{THR}, \text{EGR}) \quad (2)$$

By manipulating these equations, four residuals may be generated so that each one is insensitive to

Figure 3 Detailed fault tree of the circuit shown in Figure 2 [Reproduced from [1]. © McGraw-Hill, 2006.]

Figure 4 Car-engine manifold system and fault-to-residual structure matrix

one of the component faults, ΔTHR , ΔEGR , ΔMAP , ΔMAF , and depends on the three others:

$$r_1 = \varphi_1(\Delta\text{EGR}, \Delta\text{MAP}, \Delta\text{MAF}) \quad (3)$$

$$r_2 = \varphi_2(\Delta\text{THR}, \Delta\text{MAP}, \Delta\text{MAF}) \quad (4)$$

$$r_3 = \varphi_3(\Delta\text{THR}, \Delta\text{EGR}, \Delta\text{MAF}) \quad (5)$$

$$r_4 = \varphi_4(\Delta\text{THR}, \Delta\text{EGR}, \Delta\text{MAP}) \quad (6)$$

These four residuals form a structured set, supporting fault isolation. Their structure is also shown in Figure 4, where a “1” means that a residual

does respond to a fault while a “0” means it does not. The columns of the structure matrix are fault codes, the logic response of the residual set to each particular fault.

With an automotive diagnostic system, the critical issue is to find sufficiently general models so that a single scheme may function well across an entire automobile product line and under widely varying operating conditions [1, 7].

Federal Statistical Systems as Data Sources for Intelligence, Investigative, or Prosecutorial Work

A quantitative data analysis, and in the current instance, the quantitative analysis of risk in the context of threats to homeland security, requires at the outset appropriate and good quality data. The ultimate analysis can only be as informative as the underlying data permit. Data analysts have understood this truism both practically and theoretically. Thus, side by side with the development of the techniques of statistical analysis, statisticians and officials in agencies, public and private, that conduct quantitative analysis have been pioneers in the development, management, and preservation of quantitative data. This data development, management, and preservation process has, in turn, led to advances in standardization of techniques, from coding systems, to questionnaire and survey design, to collection procedures.

Data development thus broadly defined has, in turn, led to the creation of data archives for secondary use and related advances in the management and use of secondary data. The historical analysis of microdata from past censuses; the aggregation of transaction data for data mining (*see Early Warning Systems (EWSs) for Predicting Financial Crisis; Risk in Credit Granting and Lending Decisions: Credit Scoring*) applications; the matching of data from multiple systems in capture/recapture applications to identify issues of coverage – all these areas of research and analysis would not be possible without the preservation of large-scale data collections and procedures for providing access to these data systems for later research.

Administrative Data and Statistical Data

National states, and in the current context, the United States, have been the chief agencies for the development and preservation of statistical data about the economic, social, and political activities within their boundaries. While conducting the routine activities

of collecting and spending taxes, identifying and registering market transactions, providing benefits to individuals and organizations, regulating disputes, or monitoring and licensing activities, governments collect and record huge amounts of information. This information is “administrative” – that is collected as part of the activities of the government itself.

Such information is not necessarily tabular or “quantitative”, but in the eighteenth century analysts initially called *statists* recognized that the resulting tabular records could be the basis of a new form of knowledge, which they called *statistics*. These early statisticians recognized that records had value apart from their administrative functions. They pioneered in the development of statistical data analysis, that is, the analysis of patterns of aggregates, and eventually they led the parallel development of governmental collection of tabular data for statistical purposes only.

Governmental data systems also record information about natural phenomena, which may be compiled into statistical data. Weather readings; water levels in lakes and rivers; records of disease in people, animals, and plants; chemical analyses of foods and nutrients, to name just a few types of data systems, may also be deployed for risk analyses and general statistical analysis. For current purposes, namely, the use of governmental data sources for intelligence, investigative, and prosecutorial work, the most controversial uses of federal data systems have arisen with respect to data on individuals, groups, or organizations suspected of illegal activity or threats to national security, and the discussion below focuses on these data.

There has been a close and often confused administrative relationship between state data collections for public informational purposes and those for surveillance (*see Managing Infrastructure Reliability, Safety, and Security; Dynamic Financial Analysis Sampling and Inspection for Monitoring Threats to Homeland Security*), tax collection, benefits administration, or even military control of people. The literature on the history of state surveillance either does not acknowledge or does not distinguish well between the practices of statistical data collection and administrative data collection [1–3] or in the recent special issue of *Contemporary Sociology*, titled “Taking a Look at Surveillance Studies” [4–8]. Higgs [9] provides an explicitly historical analysis. By the early nineteenth century, when “information came of age” [10], individuals and agencies involved

in “statistical” analysis developed their own practices, logic, and rules to guarantee the integrity of their new form of knowledge. Officials in government statistical agencies recognized that the quality of the data they collected and the credibility of the analyses derived from such data could be compromised if it was seen to be part of an administrative activity of the state. Thus, they strove to separate the statistical agencies of government from those of the administrative agencies involved in the normal surveillance and policing activities of the state. They justified such a divorce on the grounds that, without administrative independence, they could not provide unbiased, accurate, precise, and trustworthy information and statistical analysis for the proper functioning of the state [11].

Over the past century, official statistical agencies have developed practices guaranteeing respondent confidentiality (for organizational and individual respondents) both for ethical and practical reasons of assuring truthful data collection. In current official statistical practice, there is a sharp distinction between data collected for an administrative purpose and those collected for a statistical or research purpose. Administrative data (*see* **Occupational Risks; Public Health Surveillance**) are data that fundamentally serve administration purposes. The administrative agency collects identifiable information on individual respondents to secure the administration of the tax, program, or service. Statistical data are essentially anonymous, concerned with distributions, patterns, and averages, and individual identifiers function to guarantee data integrity. One does not want two responses from the same business or household. Administrative data, which are to be analyzed for statistical purposes, are stripped of their identifiers and anonymized to make the data like survey data.

The two forms of quantitative data, e.g., administrative data and statistical data, look quite similar at first blush. From the respondent’s perspective, the distinctions between these two types of data are not clear. The questionnaire one fills out to apply for a benefit program, or the tax form one completes, does not look terribly different from a census or survey form. The purpose of the administrative questionnaire is clear, e.g., the intended benefit or the tax obligation. However, the public may be wary about offering information for a purely statistical questionnaire without a clear sense of how the information will be used. Over time, therefore, safeguards have

been put in place to guarantee the data are used properly and to explain the functions of statistical data.

The system of safeguards is generally called *statistical confidentiality* (*see* **Privacy Protection in an Era of Data Mining and Record Keeping; Ethical Issues in Using Statistics, Statistical Methods, and Statistical Sources in Work Related to Homeland Security**) – that is, the system of procedures that govern who can access data, how sensitive information is protected, and how data are preserved. When an individual, organization, or business enterprise responds to statistical inquiries from the federal government, be it the population census, an economic census, or a periodic survey, the questionnaire contains a pledge that the answers to the questions will be kept confidential, will be used for statistical purposes only, and that no harm can come to an individual or business from truthful responses.

This pledge, akin to the requirements that health care providers maintain confidentiality of medical records, or the guarantees received by participants from institutional review boards in research projects, is a fundamental principle of statistical practice and has been credited for making US government statistics reliable and thus an effective base upon which to build public policy. It is also a venerable pledge, dating back in the United States to presidential census proclamations of a century ago, and the efforts of generations of government officials to clarify and refine procedures [12–14].

Deploying Statistical Data for Intelligence, Investigative, or Prosecutorial Work

It is in the context of the development of the two types of quantitative data collected and used by government on people and organizations that one must consider the issues for deploying statistical data for intelligence, investigative, or prosecutorial work. The simplest and unproblematic use of statistical data in this context is the same as that in the use of such data for any policy context, namely, to define and describe the parameters and frame the extent of any particular analysis of risk. For an analysis of the quality of the screening systems at airports, what is the size of the screener labor force? How many people are screened? How long does an average screening take? What is the likelihood of a failure in the system? Which locations are busiest, and most likely to fail under stress? For a profile of drug

trafficking, can the characteristics of known violators be compared with a profile of potential suspects in a larger population, to identify the most effective use of surveillance and police resources to deter the activity? Can the characteristics of individuals infected with HIV be used to target populations for screening and prevention? In many of these applications, the data underlying the statistical analyses are themselves sampled or complete files of existing administrative records, systematized and made publicly available for research. See, for example, the special “topical” archives at the Interuniversity Consortium for Political and Social Research sponsored by federal agencies, including the National Institute on Aging; National Institute of Justice; Substance Abuse and Mental Health Services Administration (<http://www.icpsr.umich.edu/cocoon/ICPSR/all/archives.xml>).

More problematic uses of statistical data are also possible, however. Particularly in the context of a major and immediate threat to public safety and national security, the pressures on the investigative and surveillance agencies to deter the threat can lead to (a) improper use of statistical data and short cuts in the name of the emergency or (b) full-scale efforts to break the anonymized character of statistical data and in effect deploy it for surveillance purposes. Both such uses may seem appropriate in an emergency context. Both are likely to be ineffective in responding to or deterring the original threat and will also damage the integrity of the statistical system in the long run.

The pressure to make “emergency” use of inappropriate statistical data, for a “close enough” or “down and dirty” analysis, is likely to be made when the threat is at its sharpest and the public pressure to “do something” is greatest. The data analyst in this situation may well be aware that the data deployed, for example, for an ethnic profile of potential terrorists, is highly flawed, but the effort proceeds because the need seems so great (and the risk to the researcher in doing nothing is greater than that in using the flawed data). The Department of Homeland Security’s (DHS) 2003 request for a zip-code tabulation from the 2000 census of “Arabs” is an example of such a rushed and flawed data request [15]. As many commentators have noted, the request implied a blanket racist targeting of “Arabs” – in itself an improper form of analysis, and one which

arguably undermines the trust in the statistical system overall.

Further, in this instance, it appears that neither the original agency request, nor the census officials who supplied the tabulations, discussed the capacity of these particular data to provide an indicator for homeland security. The data were derived from the sample census question on “ancestry”, and thus captured any individual who identified as “Arab” – even if that meant that the respondent was reporting that one relative from several generations back had come from the “Arab” Middle East. This flaw points to a larger issue. The variables, coding systems, and sampling rates in statistical data systems of long independence, such as the census, are designed to address issues of statistical interest. Thus the “ancestry” data in the census address the issues of immigration and cultural assimilation over generations if not centuries. They do not readily translate into tabulated data that are useful for immediate investigation and surveillance. As with all data use, the analyst needs to understand the structure, logic, strengths, and limitations of the data.

The second and more troubling potential use of statistical data for surveillance emerges when an administrative agency makes an explicit request to “breach” confidentiality and deploy microdata collected under a pledge of confidentiality for “emergency” surveillance and investigative purposes. The US Patriot Act, drafted in the weeks after the attacks on the World Trade Center and the Pentagon, contained a provision (Section 508) permitting the Attorney General to access confidential data collected in the National Center for Education Statistics for investigation and prosecution of suspected terrorists [16]. This provision remains in the law, though to date, there has been no analysis of its implementation and use. Similar legislative language permitted administrative agencies access to confidential statistical data in the Commerce Department during World War II. Information from the 1940 census, economic censuses, and lists of businesses and industries was provided to both the war planning agencies and the surveillance agencies “for use in connection with the conduct of the war” from 1942 to 1947 [17].

There is limited research on the disclosures from World War II, though it is clear that the statistical agencies were quick to support repeal of the wartime measure at the end of the war. The impact on response rates of the blurring of the line between

statistical and administrative data for surveillance has also not been systematically explored, though survey research on the more general issue of “trust” indicates damage to a statistical system that violates its pledge of confidentiality [18]. There is need for continued research on the difference between surveillance data and statistical data, and for the best ways to deploy statistical data for the analysis of security concerns without jeopardizing the integrity of the statistical data in the process.

Fraud in Insurance

In insurance, fraud is defined as the attempt to hide circumstances or distort reality in order to obtain an economic gain from the contract between the insurer and the policy holder. All insurance branches are vulnerable to fraud [1]. One of the most common types of fraud occurs when the policy holder exaggerates the losses and claims compensation in an amount higher than what would have been a just and fair payment. Even in the underwriting process, information may be withheld or manipulated in order to obtain a lower premium or a coverage that otherwise would have been denied. This is called *underwriting fraud*.

The lines of business corresponding to automobile insurance, health insurance, homeowners' insurance, and worker compensation insurance are known to be frequently affected by fraud because natural claims linked to accidents are more likely to occur than any other claims. Insurers are increasingly concerned about fraud in these areas because they represent a large percentage of the total premiums earned by their companies.

One classical example of fraudulent behavior related to automobile insurance is to make an agreement with a repair shop and claim damages that had occurred to a car before a given accident as that related to that accident. An example of fraud in health insurance is withholding information about preexisting health conditions from the insurer. In homeowners' insurance, an example of a typical fraudulent action is the claim of coverage for a broken appliance (e.g., a dishwasher) as due to an electricity surge that had never taken place. In worker's compensation, fabricated claims for medical treatments are sometimes used to misrepresent and exaggerate wage losses.

Insurance fraud can be fought by prevention and detection. Prevention aims at stopping fraud from occurring and detection includes all kinds of strategies and methods to discover fraud once it has already been perpetrated. It is difficult to analyze insurance fraud because of the small amount of systematic information available about its forms and scope. The Insurance Fraud Bureau Research Register [2] located in Massachusetts provides a vast list of resources on insurance fraud. The register was created in 1993, "to identify all available research

on insurance fraud from whatever source, to encourage company research departments, local fraud agencies and local academic institutions to get involved and use their resources to study insurance fraud and to identify all publicly available databases on insurance fraud which could be made available to researchers".

Types of Fraud

First, regarding fraud committed by the insured, in the literature we find a distinction between soft and hard fraud, that is, between claims in which the damages have been exaggerated, and those comprising damages completely invented in relation to a staged, nonexistent, or unrelated accident (this kind of fraud often requires involvement of other external agents, such as health care providers or car repair shops). Criminal fraud, hard fraud or planned fraud, are illegal activities that can be prosecuted and end with convictions. Soft fraud, buildup fraud, and opportunistic fraud are terms usually applied to cases of loss overstatement or abuse, which is not illegal and more difficult to identify. In buildup fraud costs are inflated, but the damages correspond to an accident actually related to the claim. In opportunistic fraud, the accident is also real but a portion of the claimed amount is related to damages either fabricated or related to a different accident. Most soft fraud are settled by negotiations and the insurer relies on persuasion and confrontation rather than on costly or lengthy court decisions. However, court prosecution has a positive deterrence effect on fraud [3]. Individuals become aware that fraud is a criminal activity and they also see the risks of being caught [4, 5]. Insurance companies also use other classifications of fraud, usually using some specific settings or distinct circumstances as criteria.

Secondly, besides fraud committed by the insured, as discussed above, there could be internal fraud perpetrated within the insurance companies by the agents, insurer employees, brokers, managers, or representatives. They can obstruct the investigations or simply collaborate with customers in fraudulent activities.

Fraud Deterrence

The theory underlying fraud deterrence is most often based on the basic utility model for the policyholder

[6]. The individual decision to perpetrate fraud is very intuitive: the insured would file a fraudulent claim only if the expected utility is larger than the *status quo*. The expected utility is calculated using two scenarios. First, it is assumed with a certain level of probability that the fraud will be discovered, and then the fraudster would certainly lose the opportunity to get any compensation for the claim, and moreover he/she would be fined. Secondly, if the fraud is not detected, then the insured would gain an undue compensation.

Fraud prevention can only succeed if certain mechanisms that could induce one to speak the truth are in place. One example of such a mechanism already used by the insurers is the imposition of significant penalties for fraud, while another is the introduction of lower deductibles or lower premiums based on the no-claims record of the insured. The most recommended mechanism, however, is to commit the insurer to an audit strategy as often as possible, that is, to specify in advance the way in which claims are selected for audit on a regular basis. Thus, audits do not necessarily depend on the characteristics of the claims. Another efficient practice is to inform the insured and the general public that a given company makes all possible efforts to fight fraud.

The relationship between the insurer and the insured through an insurance contract should incorporate incentives for not making fraudulent claims. Once the insurer receives the claim, he or she can decide whether it is profitable to investigate it. If such investigation seems unprofitable, the claimed amount is paid without any further checking.

Any detection system should be combined with a random audit procedure [7]. In that case, any particular claim has equal probability of being investigated. In a regulated market, credible commitment can also be ensured through external fraud investigation agencies funded by the insurers.

Some studies of the theory of insurance fraud consider auditing as a mechanism to control fraud (see [6, 8]). This approach is called *costly state verification* and was introduced by Townsend [9] in 1979. It assumes that through incurring an auditing cost the insurer can obtain valuable information about the claim. It implies that the audit process using models or detection systems and special identification units always discerns whether a claim is fraudulent or not. The challenge is to design a contract that minimizes the insurer costs, including the

total claim payment and the cost of the audit. Models commonly suggested for such purposes use the claimed amount to decide about the application of monitoring techniques. In other words, deterministic audits are compared to random audits [10], or it is assumed that the insurer would commit to some audit strategy [11].

A parallel discussion concerns *costly state falsification* [12, 13], which is based on the supposition that the insurer cannot audit the claims, i.e., determine whether the claims are truthful or not. Moreover, an optimal contract design can also be applied, based on the assumption that the claimant would exaggerate the amount of the loss but at a cost greater than zero. We may conclude that the designing of an auditing strategy is linked to the specification of an insurance contract. The analysis of the contract by Dionne and Gagné [14] revealed that insurance fraud creates a significant problem with resource allocation. For instance, in the case of automobile insurance, the straight deductible contracts shape the falsification behavior of the insured. If the deductible is higher, then the probability of reporting a small loss is lower.

Vázquez and Watt [15] have proposed other theoretical solutions, such as the optimal auditing strategies that minimize the total costs incurred from buildup or the accounting for the cost of paying undetected fraud claims. Costly state verification may be used with the optimal auditing strategy but additional assumptions have to be made about claim size, audit cost, proportion of opportunistic insured, commitment to an investigation strategy, and the extent to which the insured is able to manipulate the audit costs. Recently, a transition is observed from the formal definition of an optimal claims auditing strategy to the calibration of the model on data, and to the derivation of the optimal auditing strategy.

Fraud Detection

Fraud is not self-revealed and, thus, has to be investigated. It is necessary to find evidence of fraud and determine the factors that did not protect the system from the fraudulent actions. In order to produce evidence, particularly if the case has to be proved in the court, it is often necessary to employ intensive specialized investigation skills. If the evidence is not conclusive, the cases are usually

settled with the claimant either through compensation denial or a partial payment.

Auditing strategies serve both deterrence and detection purposes [16]. An automated detection system informs the insurer which claims to audit but it often fails because it cannot adjust itself to the continuously changing environment and the emerging opportunities for committing fraud. More information is necessary and it can be obtained when longitudinal or enriched data are analyzed. A fraud detection system, to be effective, requires unpredictability since only randomness puts the perpetrator at risk of being caught. It is difficult to calculate the return on investment in detection systems because a higher fraud detection rate may reflect an increase in fraudulent activity rather than a better detection system. The calculation of costs and benefits of such a system should also take into account the fact that an unpaid claim carries a commitment effect value to the customers.

The strategies and the detection technology that an insurer can use to detect fraud do not necessarily apply to all lines of business, or all cases. There are unique ways of doing business and how firms handle claims; the kinds of products and the characteristics of the portfolios do impact the fraud detection systems. Cultural differences, habits, and social rules also play a role in this regard.

Tools for fraud detection are equally diverse. These include human resources, including external advisors, data mining, statistical analyses, and ways of monitoring. Methods used for the detection of fraudulent or suspicious claims related to human resources include fraud awareness training, video and audio tape surveillance, manual indicator cards, and internal audits and information collected from agents or informants. Methods of data analysis require collecting both external and internal information, which are processed by means of computer software, preset variables, statistical and mathematical analytical techniques, or geographic data mapping. The cost of investigating fraud is a key factor in determining implementation of a deterrence and detection strategy, and the cost of fraud has to be taken into account when the benefits of a detection strategy are considered [17, 18].

The detection model is used to help insurance companies in making decisions and to ensure that they are better equipped to counter insurance fraud. An audit strategy with a detection model has to be

part of the claims handling process. The adjusting of claims usually puts them into two categories: express paid claims (easily paid) and target claims (that need to be investigated) [19]. Target claims are screened and eventually investigated by specialized investigation units (SIUs), which either are part of the insurance company or are contracted externally (sometimes they are governmental agencies).

Fraud Indicators

Fraud indicators, often called the *red flags*, are measurable characteristics that suggest the occurrence of fraud. Some of them, such as the date of the accident, are objective, while others are subjective. One example of the latter is a binary variable indicating that when the claim was first reported the insured seemed too familiar with the insurance terminology. Often, such expertise about the way in which claims are handled is associated with fraudsters. Other possible indicators can be obtained using text mining processes, from free-form text fields that are kept in customer databases.

Table 1 shows some examples of fraud indicators for automobile insurance that can be found in [19–22].

Some indicators easily signal a fraudulent claim, while others may be misleading or wrong. For example, witnesses are usually considered a reliable source of information on how an accident occurred, but quite often they may not actually be authentic witnesses.

Table 1 Examples of fraud indicators in automobile insurance

Date of subscription to guarantee and/or date of its modification too close to date of accident
Date/time of the accident do not match the insured habits
Harassment from policyholder to obtain quick settlement of a claim
Numerous claims submitted in the past
Production of questionable or falsified documents (copies or bill duplicates)
Prolonged recovery from injury
Shortly before the loss, the insured checked the extent of coverage with the agent
Suspicious reputation of providers
Variations in or additions to the policyholder's initial claims
Vehicle whose value does not match the income of policyholder

Steps for Data Analysis in Detecting Fraud

The claims handling process is linked to the steps for analyzing data, which, for the fraud detection model, are recommended to be as follows:

1. The construction of a random sample of claims, avoiding a selection bias.
2. The identification of red flags or other sorting indicators, avoiding the subjective ones. As time passes from the initial submission of the claim, new indicators may emerge, for instance, related to medical treatment or repair bills.
3. The clustering of claims into homogeneous categories. Sometimes a hypothesis about propensity to fraud may be helpful.
4. The assessment of fraud. Claims are classified as fraudulent or honest externally; however, the adjusters and investigators may make a mistake or have different opinions.
5. The construction of a detection model. Once the sample claims are classified, supervised models provide specific characteristics to the categories of claims, and a score is generated for this purpose [22]. However, the fact that claims are classified on the basis of similarity creates a situation of potential danger because, if a fraudulent claim is identified, similar claims may be also considered fraudulent by association. Another question is whether the claims have been classified correctly or not. Some models are equipped to take a possible misclassification into account [23, 24]. It is also necessary to evaluate the prediction performance of the fraud detection model before its implementation.
6. The monitoring of the results. Expert assessment, cluster homogeneity, and model performance are the foundations of static testing. The real-time operation of the model relates to dynamic testing. The model should be fine-tuned and the investigative proportions should be adjusted to optimize detection of fraud.

From Basel II to Solvency II – Risk Management in the Insurance Sector

The Evolution of the Regulatory Framework for Banks and Insurers

In the financial industry, the rules of the committee for banking supervision at the Bank of International Settlement (BIS) in Basel have drastically changed the business in all Organisation for Economic Co-operation and Development (OECD) countries. These rules are known as the *Basel rules*. The first set of Basel rules, called *Basel I*, was launched in 1988.

The justification of a fairly elaborate regulatory framework is based on the interdependence of banks and the role of the banking sector for the overall economy. Banks represent a crucial element of the financial system that in turn, is of utmost importance for the allocation of capital and risk in an economy. Banks, just like the financial system as a whole, bring together the supply of savings and the demand for investment financing and, hence, can significantly affect the real sector of the economy. Without a stable financial system, no country can have firms with healthy financial structures, high investment expenditure, or significant R&D activities. Thus, a stable financial sector is a prerequisite for sustained economic growth and further increase of welfare. The Asian crisis is seen as a textbook example of how damaging the lack of stability in the financial system and, notably, the banking system can be.

The Basel I rules have been adopted by national laws in all OECD countries. The current directive is known under Basel II. Basel II is a rigorous extension of Basel I and will become effective in most countries within this decade.

In 2002, a regulatory framework for the European insurance sector was launched by the European Commission. This framework is called *Solvency II* which does not only sound similar to Basel II – the framework carries the Basel II capital adequacy rules for the banking sector to the determination of the minimum *solvency* (see **Solvency**) capital in the insurance sector.

The justification of a regulatory framework of the insurance sector is frequently based on the

role this sector plays as a means of diversifying risk and allocating risk to market participants who can best cope with the particular risks. In a more global economy, additional risks occur that can have important effects on the magnitude and the direction of international capital flows. Without a sound risk allocation system, risk-related decisions are likely to be suboptimal and, hence, lead to a combination of higher *volatility* (see **Volatility Modeling**), following unanticipated negative events, and to less investment. At least in the life insurance sector, there is another argument supporting a regulatory framework. This has to do with the exposure of an individual who engages in such a contract. Although future income depends heavily on the performance of the insurance company, the individual neither has possibilities to control the activities of the insurer, nor can he liquidate his assets in order to invest the funds somewhere else.

Against this background, this article analyzes two aspects of risk-management regulation. First, it illustrates how the competitive positions in the global banking system have changed as an effect of Basel II and how, analogously, Solvency II will affect the insurance industry. Secondly, since insurance risks are much more uncommon than banking risks, it illustrates how the calculation of a minimum solvency capital ratio for an insurance company is performed. This will be done for two types of insurance companies: property and casualty (P&C) insurers and life insurers.

The Future of Banking – between Markets and Institutions

In the following, three aspects (points 1–3 below) are analyzed regarding the change in the competitive positions of different banking systems due to the initiation and development of the Basel accord:

Point 1: Two different types of financial systems and the development of their competitive positions over the last 15 years are described.

Point 2: The reasons for the change in the competitive positions of these two financial systems are analyzed.

Point 3: The conclusions for the insurance sector, which can be drawn from the changes in the banking sector are analyzed.

We begin with the first point. Two pure forms of banking systems can be distinguished: more financial institution oriented systems as in Germany or Japan and more investment and capital market oriented systems as in the United States or the United Kingdom. The competitive positions of the two pure forms of banking systems have changed significantly since 1988. Since then, banking has become much more market oriented and less affected by financial institutions. The league table of the biggest banks worldwide reflects this change in the global financial system: in 1990, six Japanese banks were ranked among the top six banks in terms of market capitalization and Deutsche Bank was ranked number seven. Barclays, National Westminster, and JP Morgan were the biggest Anglo-Saxon banks ranked 8–10, respectively. In 2005, the biggest bank was the Citigroup. Deutsche Bank was ranked 25 and none of the Japanese banks was ranked among the top 15 banks anymore. This is a dramatic change within only 15 years.

Of course, we can wonder what the reasons were for this dramatic change. This leads us to the second point of our considerations. A major source driving this change is regulation. The Basel accord, launched in July 1988, has enhanced the process of the capital market orientation of the global banking system very considerably. Basel I, the first Basel accord, is still effective. It requires OECD banks to hold equity capital according to the risk of asset and liability positions. Basel II, which has been very intensively discussed since 1999 and which will become effective in the OECD banking industry soon, will strengthen the process of capital market orientation even more. Before the Basel accord was designed, balance sheet risks in banks were covered by a standardized equity fraction of 8% of the assets. This figure has not been supported by valid risk data, it was rather based on intuition. The Basel accord applied risk weights to each balance sheet position, i.e., low risks imply low equity ratios and, therefore, higher returns on equity. Higher risks require a higher amount of comparatively expensive equity capital. Before the launch of Basel I, the more beneficial the bank transactions, the more riskier they were. Banks were particularly successful in environments in which financial institutions were strong. Japan and Germany are two examples for countries with relatively strong financial institutions, but relatively weak financial

markets compared to the United Kingdom and the United States.

Before the Basel accord was launched, a loan to a noninvestment-grade counterparty used to be covered by the same amount of equity capital like a loan to a first-class counterparty. Obviously, since the expected return on a low-rated counterparty is higher than on counterparties with higher ratings (*see Risk in Credit Granting and Lending Decisions: Credit Scoring*), this rule creates incentives for loans with parties that have poor credit qualities and makes loans to first-class counterparties less attractive. Under the Basel II accord, the equity coverage of a bank loan depends on the credit rating of the counterparty. One important effect is that banks tend to buy much more hedging and diversification instruments for credit risk in the capital markets. New asset classes like credit derivatives, collateralized debt obligations, or asset backed securities were created during the same time the Basel rules were developed. All of these instruments are capital market instruments. Product innovations have not only been observed for credit risks, but also for hedging and diversifying interest rate, foreign exchange, commodity price, and stock market risks.

At the same time, banks in countries with a traditional strong capital market orientation have become stronger and gained capitalization weight. The lack of a developed investment banking industry in Germany and Japan compared to very strong US and UK investment banks caused the market capitalization of German and Japanese banks to significantly lag behind their Anglo-Saxon counterparts in the last 15 years. Basel I and Basel II are shifting risk management away from financial institutions toward more transparent capital markets. This negative consequence for the German and the Japanese banks has obviously been underestimated by bank lobbyists in countries with emphasis on strong bank orientation.

These arguments lead to our third and last point of our considerations, namely, how the experience from the banking system will be transferred to the insurance sector. In February 2002, the European Commission launched a regulatory framework for the European insurance industry. This framework is referred to as *Solvency II*. Solvency II adopts the Basel II three pillars of prudential regulation to the insurance sector. Probably from 2008 onward, Solvency II will affect European insurance companies very significantly. The major goal is, like Basel II,

to achieve more transparency for the regulators and the public. This is reached by adapting the minimum solvency capital (MSC) in an insurance company, to its risks. The question now is whether such a regulatory shift will affect the insurance business to the same extent as was the case in the banking sector. Insurance risks used to be completely institutionalized. The market for capital market instruments securitizing (*see Securitization/Life*) typical insurance risks is not yet very developed. Insurance institutions diversify insurance risks and nondiversifiable insurance risks are reinsured with re-insurance companies. However, the exciting question is whether the past developments of the banking industry are going to be future trends in the insurance sector. It is not unlikely that we will observe capital market products securitizing typical insurance risks like catastrophe or weather risks in the P&C sector, and longevity or mortality risks in the life sector. Examples for derivatives on all of these risks already exist. Hence, the insurance sector has not yet gone as far as the banking sector. This is the case because the Solvency II initiative is much younger than the Basel rules. One should also not forget that Solvency II is currently a European and not yet a global initiative. This is also a reason for a slower shift of insurance risks toward capital markets than we observe for formerly typical bank risks. However, the development towards the capital market in the insurance sector has already begun. Instruments like weather derivatives, cat bonds (catastrophe bonds), or longevity bonds are not yet extremely common, but they exist and are gaining significance. We observe many indicators that predict a development away from an institutional orientation toward a market orientation of the insurance sector. Currently, the still powerful insurance companies should watch the development very carefully and should have in mind what happened earlier to the formerly powerful European banks.

Risk Management for P&C Insurers

Although the Solvency II framework is very closely related to Basel II, the implementation of a risk-management framework for insurers is more than just a simple application of a value at risk (VaR) measurement model to an insurance portfolio. Insurance companies deal with risk classes that are completely different from those of banks. This holds for both

types of insurance business, i.e., P&C as well as life insurance.

The determination of the joint probability distribution of all risks is done based on a dynamic financial analysis (DFA) approach as described by, for example, Kaufmann *et al.* [1]. The DFA goal is to identify the MSC of an insurance company. The MSC is the amount of capital required to provide a given level of safety to policy holders over a specified time horizon, given the enterprise-wide risk distribution of the insurer. Hence, the MSC is comparable to the VaR, which we know very well from bank risk management.

Figure 1 illustrates the transmission mechanism of a comparatively simple DFA model for the factors affecting the insurer's assets and liabilities. The figure shows that there are 10 probability distributions, which are needed to characterize the following 8 risk factors: interest rates, inflation, stock market returns, credit risk (i.e., the risk for a reinsurer's default), risk in the growth rate in the number of contracts, catastrophic- and noncatastrophic-risks, and the pattern of the payments over time which follows an insurance event.

The joint probability distribution of these risk factors expresses the distribution for the loss reserves of the insurance company. This cannot be determined analytically. A computation of the MSC must therefore be based on a simulation approach. DFA is such a simulation approach. Figure 2 shows an example of the joint distribution of the loss reserves. Both, the catastrophe and the noncatastrophe distribution depend on two single probability distributions, namely, loss frequency and loss severity. Severity is typically modeled as lognormal distribution. The frequency for catastrophe losses is often modeled by a Poisson distribution (*see Logistic Regression*) while noncatastrophe loss frequencies are characterized by normal distributions. Hence, the joint loss reserves distribution in Figure 2 is made up by four nonstandard probability distributions. The joint distribution can therefore not be expressed in analytical terms.

Risk Management for Life Insurers

While the preceding section dealt with P&C insurers, this section addresses the risk management of life insurance companies. The situation in determining the MSC is completely different from P&C insurers. While the complexity of risk factors was most

Figure 1 Transmission mechanism of the DFA analysis for a P&C insurer

Figure 2 Noncatastrophe losses and catastrophe losses generate the distribution of the loss reserves

important in the P&C sector, there are two dominant risk factors in the life insurance business. These are interest rate risks and biometric risks (e.g., longevity).

What makes the risk management of life insurance contracts complicated are the number and the complexity of the embedded options in such contracts. Figure 3 summarizes the most important risks in the life insurance business. It shows that a life insurance contract can be considered as a combination of a risk-free bond, an interest rate bonus option, and a surrender option.

One of the best known options in life insurance contracts is the bonus option, guaranteeing

a minimum return to the policy holder (*see Bonus–Malus Systems*). This option depends on the interest rate situation on the capital market. It can therefore be hedged by fixed income derivatives, which are traded at the financial markets typically with great liquidity. The risk management of the bonus option is therefore comparable to interest rate risk management in the banking sector.

The surrender option indicated in Figure 3 is more difficult to handle. It provides the policy holder's contract with an early liquidation feature. The early liquidation likelihood is due to changes in market or regulatory conditions. It might therefore be driven

Figure 3 Risks affecting the assets and liabilities of life insurance companies

by changes in the tax regime associated with life insurance contracts. Moreover, the early liquidation likelihood does also depend on the interest rate scenario in the capital market: the higher the interest rates are, the higher will be the likelihood of an early exercise. Förterer [2] estimates the value of the early liquidation option to be roughly 5% of the entire liability value.

Finally, for the valuation and the risk management of a life insurance contract, it is not sufficient to apply the VaR (*see Value at Risk (VaR) and Risk Measures*) tools developed for bank risk management. There is a recent literature dealing with the evaluation of life insurance contracts. Two excellent examples for this literature are Grosen and Jorgensen [3] or Neilson and Sandmann [4].

Conclusions

Basel II has enhanced the capital market orientation of the banking sector very significantly. Since 2002, Solvency II is a regulatory framework of the European Commission for the regulation of the European insurance sector. Since Solvency II takes Basel II as its archetype, this article deals with the question whether a much stronger capital market orientation can also be expected for the insurance sector. The conclusion is that it is very likely that more and more insurance risks will be transferred to the capital market, although insurance risks deviate from bank risks in many respects. This article also shows the most important risk factors in the P&C insurance sector

and points to the DFA as the most frequently used tool to deal with these risks.

Game Theoretic Methods

After the September 11, 2001, terrorist attacks on the World Trade Center and the Pentagon, and the subsequent anthrax attacks in the United States, there has been an increased interest in security. However, security problems pose some significant challenges to conventional methods for risk analysis [1, 2]. One critical challenge is the intentional nature of terrorist attacks [3].

Protecting against intentional attacks is fundamentally different from protecting against accidents or acts of nature. In particular, an adversary may adopt a different offensive strategy in response to observed security measures, in order to circumvent or disable those measures. For example, Ravid [4] argues that since the adversary can change targets in response to defensive investments, “investment in defensive measures, unlike investment in safety measures, saves a lower number of lives (or other sort of damages) than the apparent direct contribution of those measures.” Game theory [5] (*see Managing Infrastructure Reliability, Safety, and Security; Optimal Risk-Sharing and Deductibles in Insurance; Risk Measures and Economic Capital for (Re)insurers*) provides a way of taking this into account. In particular, game theory identifies the optimal defense against an optimal attack. While it may not be possible to actually predict terrorist attacks, protecting against an optimal attack can arguably be described as conservative. This article discusses approaches for applying game theory to the problem of defending against intentional attacks.

Applications of Game Theory to Security

Game theory has a long history of being applied to security, beginning with military applications [6–10]. It has also been extensively used in political science [11–13]; e.g., in the context of arms control. Recently, game theory has also been applied to computer security [14, 15]. Many applications of game theory to security have been by economists; see, for example [16–27]. Much of this work has been designed to provide “policy insights” [25] – e.g., on the relative merits of public *versus* private funding of defensive investments [23], or deterrence *versus* defense [19, 20, 22, 27]. Since the events of September 11, however, there has been increased

interest in using game theory not only to explore the effects of different policies, but to generate detailed guidance in support of operational-level decisions (*see Experience Feedback*) – e.g., which assets to protect, or how much to charge for terrorism insurance.

For example, Enders and Sandler [18] and Hausken [21] study substitution effects in security. Enders and Sandler observe that “installation of screening devices in US airports in January 1973 made skyjackings more difficult, thus encouraging terrorists to substitute into other kinds of hostage missions.” Similarly, they note, “If . . . the government were to secure its embassies or military bases, then attacks against such facilities would become more costly on a per-unit basis. If, moreover, the government were not at the same time to increase the security for embassy and military personnel when outside their facilities, then attacks directed at these individuals (e.g., assassinations) would become relatively cheaper” (and hence, presumably, more frequent).

Clearly, security improvements that appear to be justified without taking into account the fact that attacks may be deflected to other targets may turn out to be wasteful (at least from a public perspective) if they merely deflect attacks to other targets of comparable value. Therefore, the Brookings Institution [28] has recommended that “policy makers should focus primarily on those targets at which an attack would involve a large number of casualties, would entail significant economic costs, or would critically damage sites of high national significance.”

The Brookings recommendation constitutes a reasonable “zero-order” suggestion about how to prioritize targets for investment. However, it is important to go beyond the zero-order heuristic of protecting only the most valuable or potentially damaging targets, to account for the success probabilities of different attacks, since terrorists appear to take the probability of success into account in their choice of targets. For example, Woo [29] has observed that “al-Qaeda is . . . sensitive to target hardening,” and that “Osama bin Laden has expected very high levels of reliability for martyrdom operations.” Thus, even if a successful attack against a given target would be highly damaging, that target may not merit as much defensive investment as a target that is less valuable but more vulnerable (and hence, more attractive to attackers).

Early models that take the success probabilities of potential attacks into account include [29–31].

Both the Brookings recommendations [28] and the results in [30] still represent “weakest-link” models (*see* **Extreme Values in Reliability**), in which defensive investment is allocated only to the target(s) that would cause the most damage if attacked. However, such weakest-link models can be unrealistic in practice. For example, Arce and Sandler [16] note that weakest-link solutions “are not commonly observed among the global and transnational collective action problems confronting humankind.” In particular, real-world decision makers typically “hedge” by defending additional targets, to cover contingencies such as misestimating which targets are most attractive to attackers.

The models in [29] and [31] achieve the more realistic result of defensive hedging at optimality, but do so with a restrictive (and possibly questionable) assumption. In particular, these models assume that the attacker can observe “the marginal effectiveness of defense... at [each] target” [31], but not which defenses have been implemented. More recent work [32, 33] achieves the result of defensive hedging at equilibrium in a different manner – assuming (perhaps conservatively) that attackers can observe defensive investments perfectly, but that defenders are uncertain about the attractiveness of possible targets to the attackers. Interestingly, hedging does not always occur even in this model. In particular, the results suggest that it is often optimal for the defender to put no investment at all into some targets – especially when the defender is highly resource constrained, and the various potential targets differ greatly in their values (both of which are likely to be the case in practice).

Recently, researchers have begun to focus on allocation of defensive resources in the face of threats from both terrorism and natural disasters [34–36]. In addition, some researchers have begun formally taking into account the effect of deterrence or retaliation on terrorist recruitment; see for example [24, 37].

Security as a Game between Defenders

The work discussed above views security primarily as a game between attacker and defender. However, defensive strategies adopted by one agent can also affect the incentives faced by other defenders. Some types of defensive actions (such as installation of visible burglar alarms or car alarms) may increase

risk to other potential victims (a negative externality), leading to overinvestment in security. Conversely, other types of defensive actions – such as vaccination, fire protection, or use of antivirus protection software – decrease the risk to other potential victims (a positive externality). This type of situation can result in underinvestment in security, and “free riding” by defenders [21, 25].

To better account for security investments with positive externalities, Kunreuther and Heal [38] propose a model of interdependent security (IDS) in which agents are vulnerable to “infection” from other agents; Heal and Kunreuther [39] apply this model to the case of airline security. More specifically, this body of work assumes that the consequences of even a single successful attack would be catastrophic – leading, for example, to business failure. Under this assumption, Kunreuther and Heal show that failure of one agent to invest in security can make it unprofitable for other agents to invest, even when they would otherwise do so. Moreover, this game can have multiple equilibrium solutions (e.g., one in which all defenders invest in security, and another in which none invest), so coordinating mechanisms can help ensure that the socially optimal level of investment is reached.

Recent work [40] has extended these results to attacks occurring over time (rather than a “snapshot” model). In this case, differences in discount rates among agents can lead some agents with low discount rates not to invest in security, if other agents (e.g., those with high discount rates) choose not to invest. Thus, heterogeneous time preferences can complicate the task of achieving security.

Unlike the above work, Keohane and Zeckhauser [22] consider both positive and negative externalities among defenders. In particular, they note that reduction of population in a major city (e.g., because of relocation decisions by members of the public) may make all targets in that city less attractive to terrorists, while government investment to make a location safer will tend to attract increased population, making that location more attractive to potential attackers.

Combining Risk Analysis and Game Theory

Conventional risk analysis does not explicitly model the adaptive response of potential attackers, and hence may overstate the effectiveness and cost-effectiveness of defensive investments. However,

much game-theoretic security work focuses on non-probabilistic games. Even those models that explicitly consider the success probabilities of potential attacks – e.g., [29–33, 36, 38–40] – generally treat individual assets in isolation, and fail to consider their possible role as components of a larger system. Therefore, combining risk analysis with game theory could be fruitful in studying intentional threats to complex systems such as critical infrastructure (*see Managing Infrastructure Reliability, Safety, and Security*).

Hausken [41] has integrated probabilistic risk analysis and game theory (although not in the security context), by interpreting system reliability as a public good, and considering the incentives of players responsible for maintaining particular components of a larger system. In particular, by viewing reliability as a game between defenders responsible for different portions of the system, he identifies relationships between the series or parallel structure of the system being analyzed and classic games such as the coordination game, battle of the sexes, chicken, and prisoner’s dilemma.

Rowe [42] argues that the implications of “the human variable” in terrorism risk have yet to be adequately appreciated, and presents a framework for evaluating possible defenses in light of terrorists’ ability to “learn from experience and alter their tactics”. This approach has been used in practice to help prioritize defensive investments among multiple potential targets and threat types. Similarly, Paté-Cornell and Guikema [43] discuss the need for “periodic updating of the model and its input” to account for the dynamic nature of terrorism, but do not formally use game theory.

Banks and Anderson [44] apply similar ideas to the threat of intentionally introduced smallpox. Their approach embeds risk analysis in a game-theoretic formulation of the defender’s decision, accounting for both the adaptive nature of terrorism, and also uncertainty about the costs and benefits of particular defenses. They conclude that this approach “captures facets of the problem that are not amenable to either game theory or risk analysis on their own”.

Bier *et al.* [30] use game theory to study security of simple series and parallel systems, as a building block to more complex systems. Results suggest that defending series systems against intentional attack is extremely difficult, if the attacker knows about the system’s defenses. In particular, the attacker’s ability

to respond to the defender’s investments deprives the defender of the ability to allocate defensive investments according to their cost-effectiveness; instead, defensive investments in series systems must equalize the strength of all defended components, consistent with results in [8]. Recent work [45] begins to extend these types of models to more complicated system structures (including both parallel and series subsystems).

Conclusions

As noted above, protecting complex systems against intentional attacks is likely to require a combination of game theory and risk analysis. Risk analysis by itself does not account for the attacker’s responses to security measures, while game theory often deals with individual assets in isolation, rather than with complex networked systems (such as computer systems, electrical transmission systems, or transportation systems). Approaches that combine risk models and game-theoretic methods can take advantage of the strengths of both approaches.

VICKI M. BIER

Gene–Environment Interaction

Broad Concept

Whether nature or nurture is the predominant determinant of human traits has been a source of societal and scientific discussions for much of the last century. More recently, at least in the fields of medicine, epidemiology, and toxicology, discussion has moved away from the questions of which influence predominates and, instead, has focused on developing a fuller understanding of how genetic makeup and history of environmental exposures work together to influence an individual's traits, particularly susceptibility to diseases. This newer focus is the essence of a broad concept of gene–environment interaction: the extensive interplay of genetics and environment on risk of disease.

Closely related to this broad view of gene–environment interaction is the idea of a multifactorial or complex disease. Few diseases can be considered to have a single genetic or environmental origin; most involve influences of both types. In this context, “environment” is usually broadly construed and may include virtually anything other than “genes”. Environment could encompass things such as exposure to chemical toxicants, infectious organisms, dietary or nutritional factors, aspects of lifestyle such as smoking or exercise habits, hormonal milieu, and social dynamics associated with, for example, employment or marriage (*see* **Environmental Hazard**). Environmental factors could act anytime from conception onward throughout life. Complex diseases like cancer, asthma, and schizophrenia are widely viewed as arising from genetic predisposition, potentially involving many genes, acting together with any number of environmental factors throughout a lifetime. The complexity of sorting out the mutual influences of genes and environment on disease risk is clearly monumental.

Despite the evident challenge, the study of gene–environment interaction potentially offers substantial benefits to science and society. Consider the example of cancer. Environmental exposures appear to contribute to most cancer, but evidence is accumulating that polymorphisms in various genes, particularly metabolism and DNA-repair genes, may modulate

the effect of these exposures and, thereby, influence susceptibility [1]. Eventually, a fuller understanding of the joint effects of genetic and environmental risk factors could lead to new public health interventions that reduce cancer incidence and new clinical approaches that treat it or prevent recurrence. By identifying susceptibility genes and the metabolic pathways through which they act, one might uncover previously unrecognized carcinogens or novel genetic targets for therapeutics. Studies directed at genetically susceptible subpopulations might better delineate low levels of risk attributable to common exposures whose role was not previously recognized. A widespread exposure, even one that induces only a small increase in risk, can contribute substantially to a population's cancer burden and may, after careful risk assessment, warrant public health intervention. On the other hand, a rare genetic variant that, in the presence of certain exposures, increases an individual's risk of disease substantially would have little population-wide import but an intense impact on the few individual carriers – a situation where individually tailored counseling or clinical intervention would be invaluable.

Heterogeneity of Effect

Although the broad concept of gene–environment interaction provides the outlook and long-term goals that motivate much current biomedical research, the actual work is more restricted in scope, typically limited in any individual report to a few genes and a few exposures. Consequently, most of the statistical or methodological work that underpins current studies addresses a much narrower concept of gene–environment interaction, one that can be illustrated by considering a single genetic polymorphism and a single exposure factor. In this simple context, a defining question for this narrow concept of gene–environment interaction is whether the influence of the polymorphism and exposure together on some measure of disease risk is different from that expected based on combining their individual contributions. An equivalent question is whether the influence of one factor (e.g., exposure) differs across levels of the other factor (genotype). Thus, this narrower concept of gene–environment interaction involves heterogeneity in the statistically assessed “effect”, whether risk-enhancing or risk-reducing, of one factor across levels of the other factor.

A widely cited example of unambiguous gene–environment interaction is the disease phenylketonuria (PKU), which can lead to mental retardation [2]. A typical diet contains a certain level of the amino acid phenylalanine. Individuals who carry two defective copies of the gene whose protein product converts phenylalanine to tyrosine develop symptoms of PKU when they consume a typical diet. When these individuals consume a diet with highly restricted levels of phenylalanine, they have no symptoms. Similarly, individuals with at least one functional copy of the gene metabolize phenylalanine properly and show no symptoms. Thus, PKU requires both the genetic variant and the exposure; absence of either eliminates the adverse outcome. In this example, the outcome when genotype and exposure occur together clearly exceeds the outcome predicted on the basis of either factor alone.

While the PKU example is classic, deciding whether gene–environment interaction exists is rarely so clear-cut. In fact, the defining question itself remains ambiguous until one specifies precisely what the phrase “expected based on each individually” means. Disease outcomes might be measured on a binary scale (present or absent), an ordered categorical scale (none, mild, moderate, or severe), or a continuous scale (survival time or blood levels of some key biomarkers). Similarly, an environmental factor might be assessed on any of these scales, though genetic factors are typically assessed as binary (variant allele present or not) or categorical (zero, one, or two copies of a variant allele). Certainly, in different contexts, different statistical models would be used and implicitly set different baselines for measuring interaction. Even within a single context, alternate statistical models could be employed. A widely used class of statistical models is the generalized linear model where the outcome Y , conditional on predictors, has a distribution in the exponential family, which admits binary or continuous outcomes. In a regression setting, with a single predictor G measuring genotype and a single predictor E measuring exposure, one might model the expected value (mean) of Y conditional on G and E , $\mu(Y|G, E)$, as depending on G and E through

$$h(\mu(Y|G, E)) = \beta_0 + \beta_G G + \beta_E E \quad (1)$$

Here β_0 , β_G , and β_E are regression coefficients and $h(\cdot)$ is a strictly monotone function known as a *link*. $h(\cdot)$ could represent, among others, the identity

function, logarithmic function, or logit function. This regression model specifies that, in an outcome scale determined by $h(\cdot)$, the expected change in mean outcome corresponding to a one-unit change in E is β_E regardless of the value of G . Similarly, of course, the expected change in mean outcome corresponding to a unit change in G is β_G regardless of the value of E . Model (1) defines an expected outcome based on G and E , where the effects of G and E are additive in the scale defined by the selected link $h(\cdot)$. Thus, equation (1) provides an additive model for scale $h(\cdot)$ and represents a no-interaction null model for that scale. If, for example, G is binary and E is continuous, equation (1) describes $h(\mu(Y|G, E))$ as two parallel lines.

Among many possible ways to model departure from additivity, a simple, convenient, and often used regression model is the following:

$$h(\mu(Y|G, E)) = \beta_0 + \beta_G G + \beta_E E + \beta_{GE} G \cdot E \quad (2)$$

The product or interaction term, $\beta_{GE} G \cdot E$, encodes a departure from the additive expected joint influence of G and E defined by equation (1). Thus, equation (2) embodies the idea that the outcome of G and E together differs from that expected from summing their individual contributions. In equation (2), again in the scale specified by $h(\cdot)$, the change in mean outcome corresponding to a unit change in E is $\beta_E + \beta_{GE} G$, a quantity that depends explicitly on G . A similar expression, depending on E , applies for the change in mean outcome for a unit change in G . Whenever $\beta_{GE} \neq 0$, gene–environment interaction is said to exist because the change in mean outcome associated with exposure differs across genotypes (alternatively, the change associated with genotype differs across exposure).

In epidemiology where the outcome is often binary (1 = disease present, 0 = disease absent), Y has a Bernoulli distribution with a conditional mean $\mu(Y|G, E)$. In fact, $\mu(Y|G, E)$ in this setting is the conditional probability of disease given the values of G and E , denoted by $\Pr(Y = 1|G = g, E = e)$ or by P_{ge} . Under equation (1), algebraic manipulations yield

$$h(P_{ge}) - h(P_{g0}) - h(P_{0e}) + h(P_{00}) = 0 \quad (3)$$

as a condition that must hold for interaction to be absent in the scale specified by link $h(\cdot)$. Taking g and e as positive and working with equation (2), one can

show that the left-hand side of equation (3) is positive whenever the coefficient β_{GE} is positive (sometimes called a *superadditive* or *synergistic interaction* because the expected outcome when G and E occur together is larger than expected under the additive model). Alternatively, the left-hand side of equation (3) is negative whenever β_{GE} is negative (sometimes called a *subadditive* or *antagonistic interaction* because the expected outcome when G and E occur together is smaller than expected under additivity).

An important characteristic of the narrow concept of gene–environment interaction enunciated above is that it is fundamentally a statistical concept of interaction, one that is defined in terms of coefficients in regression models with no necessary implication of causality. The modeling process provides a quantitative description of the joint influence of G and E . For data analysis, the choice of model is somewhat arbitrary, though limited to an extent by the type of outcome, owing to the imperative to use a model that fits the observed data well, and by any constraints imposed on what models might be estimable under the sampling design of the study. To the extent that the model itself is arbitrary, whether or not gene–environment interaction exists is also arbitrary. Suppose that data are available from a cohort study and a referent or “zero” level is designated for both G and E . If the link is the identity function, $h(P) = P$, the condition specified in equation (3) would involve differences of risk differences being zero, namely,

$$(P_{ge} - P_{g0}) - (P_{0e} - P_{00}) = 0 \quad (4)$$

If instead the link is the natural logarithm function, equation (3) would be equivalent to a certain ratio of relative risks being unity, namely,

$$\frac{RR_{ge}}{(RR_{g0} \cdot RR_{0e})} = 1$$

where

$$RR_{GE} = \frac{P_{GE}}{P_{00}} \quad (5)$$

This derived condition indicates why an additive model for the logarithm of risk is often described as a *multiplicative model* for relative risk. Similarly, for commonly used logistic regression where the link is the logit or log-odds function, equation (3) would correspond to a certain ratio of odds ratios being unity, namely,

$$\frac{OR_{ge}}{(OR_{g0} \cdot OR_{0e})} = 1$$

where

$$OR_{GE} = \frac{P_{GE}(1 - P_{00})}{(1 - P_{GE})P_{00}} \quad (6)$$

These three no-interaction conditions are distinct except in certain degenerate cases (e.g., $P_{0e} = P_{00}$) or in certain limits (e.g., OR s approximate RR s for rare diseases). In general, degenerate cases aside, if there is no interaction under a given link (e.g., logarithmic), there must be interaction under an alternate link (e.g., identity) and *vice versa*. Thus, the presence or absence of gene–environment interaction generally depends on the statistical model used to assess effects (see reference [3] for a numerical example). By the same token, a superadditive interaction under one link can correspond to a subadditive interaction under another.

On the other hand, some states of nature may correspond to the presence of interaction ($\beta_{GE} \neq 0$) regardless of the link function considered. Suppose that both G and E are binary (so that $g, e \in \{0, 1\}$ where 1 = “present”, 0 = “absent”) and further suppose that $P_{11} > P_{01} = P_{10} = P_{00}$ (this configuration, sometimes called *pure interaction*, corresponds to the synergistic interaction of the PKU scenario described earlier). Here, the no-interaction conditions for all three specific link functions fail to hold; and, in fact, equation (3) cannot be satisfied for any strictly monotone link function. Interactions, like the one in this example, that cannot be transformed by changes in outcome scale are sometimes called *qualitative interactions*. With two binary predictors, qualitative interactions would typically involve risk-enhancing effects of exposure for one genotype but null (or even risk-reducing) effects of exposure for the other genotype. Interactions that are not qualitative are called *quantitative*.

Causal Interactions

The concept of interaction as heterogeneity of effect on a specified outcome scale is a satisfactory one for many purposes. If a model aptly describes the data at hand, inferences based on that model can be scientifically useful. On the other hand, knowing that a statistical model on a certain scale requires an interaction term to adequately describe data may not tell the scientist anything fundamental about the underlying causal mechanism. In this sense, interaction *versus* no interaction is essentially a descriptive distinction;

if genotype and exposure together provide a larger effect than either alone, whether or not that larger effect is designated as interaction or simply as additive depends on the scale chosen.

The term “interaction” is widely used in scientific discussion and can mean a variety of things – most of which have causal implications distinct from the statistical meaning involving heterogeneity of effect discussed so far. Suppose that an epidemiologic case–control study of a disease has, through logistic regression analysis, revealed a synergistic gene–environment interaction. The underlying biological mechanism that explains how the gene and the exposure work together to cause disease remains to be dissected and understood in terms of signal transduction or enzymatic reactions or other cellular and physiologic processes. Clearly, such an effort goes well beyond any epidemiologic data at hand and requires integration of multiple lines of research. Elucidating the underlying causal mechanism would certainly be described as explaining the interaction of the gene and the exposure.

Relying almost exclusively on observational studies, rather than randomized experiments, to develop an understanding of disease risks, epidemiologists are naturally interested in inferring causal relationships from observational data. Consequently, they would like to use such data to infer truly causal interactions (not simply heterogeneity in statistical “effect”) without waiting for additional extensive laboratory work to have dissected mechanistic details. The idea of a causal interaction in epidemiology is that of “the interdependent operation of two or more causes to produce disease” [4]. Arguments based on counterfactuals or on sufficient causes both point to risk differences (i.e., use of the identity link as in equation (4)) as appropriate for assessing causal interactions when both the genetic and environmental factors are risk-enhancing and binary [5, 6] (when one or both factors are risk-reducing other links may be appropriate for assessing causal interactions [7]). Since the PKU example mentioned earlier departs from additivity in risk, it would be deemed a causal interaction, a conclusion confirmed by the known biological mechanism. Toxicologists use a closely related concept of causal interaction defined as departures from simple independent action [8], a concept of probabilistic independence, where the causes have completely separate modes of action. This latter concept has been adapted to studying causal

interactions in epidemiologic cohort studies through models like equations (1) and (2) using link $h(P) = \ln(1 - P)$ [7]. Some writers restrict application of the terms “synergy” or “superadditivity” and “antagonism” or “subadditivity”, mentioned earlier, to causal interactions.

The use of causal concepts and the associated specific links to determine whether observational data are consistent with a causal gene–environment interaction adds an interpretation beyond that offered by merely observing a statistical interaction with an arbitrary link. A causal inference of synergy would suggest that the gene and exposure do not act independently through separate pathways. A causal inference of antagonism might suggest competition for receptors. Thus, the ability to infer a causal interaction holds a clear advantage because it can offer clues regarding mechanisms of action. However, inference about causal interactions does have limitations. For example, in the counterfactual context, departures from risk additivity as in equation (4) imply the presence of causal interaction, whereas risk additivity does not necessarily imply its absence [5]. Unmeasured intervening variables pose problems for interpretation in that one set of observed data can be consistent with a several causal scenarios [9]. Likewise, when individuals vary in inherent susceptibility to the factors under study, causal interactions may be masked or may spuriously appear [7]. Cautious interpretation of any interaction declared causal by these approaches is warranted. In the epidemiological literature, causal interactions as discussed here are usually referred to as *biological interactions*. This terminology is justifiable in that the causal processes of health and disease are mediated through biology. Nevertheless, the terminology seems less than apt because the no-interaction or independence models employed are not derived from explicitly biological mechanisms such as kinetics or signaling; instead, they are predicated on philosophical concepts about what it means for two causes to act independently versus to interact.

Statistical Inference and Design

To this point, the presentation has centered on various definitions of gene–environment interaction; what remains is to consider how to test whether an interaction is present, how to estimate measures of

interaction, and how to design studies that are able to accomplish those tasks efficiently.

As discussed earlier, generalized linear models are often appropriate for analyzing data to address questions of gene–environment interaction. In these models, testing and estimation are usually accomplished *via* likelihood-based methods [10]. Equation (2) may be fitted by maximum likelihood techniques to provide estimates of model parameters and their standard errors. Wald tests and confidence intervals for β_{GE} , the interaction parameter, provide one route for inference about gene–environment interaction; alternatively, likelihood ratio tests and profile likelihood confidence intervals are available. Equation (2) could be elaborated to include multiple genetic or environmental predictors as well as their interactions. Higher-order interaction terms involving products of three or more variables might be considered although such higher-order terms may be difficult to interpret.

Detection of gene–environment interactions using generalized linear models requires larger sample sizes, often substantially larger, than those needed for detection of genetic or environmental effects alone – particularly when one or both factors are rare. This circumstance has prompted several proposals for increasing a study’s power to detect such interactions. One approach is to focus tests of interaction from a larger to a smaller set of parameters, a set anticipated to carry most of the effect. For example, with G and E categorical, an analogue of Tukey’s single degree of freedom test for interaction provides such a reduction in dimension [11]. A second general approach is to devise strategies that enrich a study sample for rare exposures or genotypes compared to their population prevalences. Proposals along these lines include counter matching [12], enrichment through relatives of cases [13], and various two-stage sampling plans that allow oversampling with defined probability [14–16]. A third approach involves exploiting a particular independence assumption. With a binary outcome, gene–environment interaction can be tested and a measure of interaction estimated using cases only (no control subjects) under the assumption that the genotype and the exposure occur independently in the population at large and the disease is rare [17]. This design, by exploiting the key assumption, increases the power for detecting gene–environment interaction compared to a case–control study with

the same number of cases and any number of controls; but it sacrifices the ability to test or estimate the main effects of genotype or of exposure. The assumption can also be exploited with case–control data (*see Case–Control Studies*) to increase the power for detecting gene–environment interaction as well as for the main effects [18, 19]. Inferences are subject to bias whenever the key assumption fails to hold [20], so these methods should be used circumspectly.

Confounding is an omnipresent source of bias in observational studies, and studies involving gene–environment interaction are no exception. Of particular concern are possible effects of hidden genetic population structure. Genetic epidemiologists can largely overcome this source of bias through the use of case-parents design – recruiting families with one affected offspring and two biological parents. Consider the situation where the genetic factor is a diallelic single nucleotide polymorphism (SNP). With this design, cases are stratified according to the genotypes of both parents. Assuming that gametes assort and are transmitted at random (Mendelian transmission) and that survival is nondifferential from conception to the time of study, the expected proportion of each allele at the SNP locus in each stratum is known under the null hypothesis. Deviations from those expected proportions provide evidence that the inherited SNP is associated with the disease within families. This same idea can be used to study gene–environment interaction while avoiding potential bias from population structure [21, 22]. Unbiased estimation of the interaction parameter requires independence between transmission of the SNP and exposure in offspring, conditional on parents’ genotypes, a weaker assumption than independence of G and E in the source population. A drawback to the case-parents design is that, while genetic main effects and gene–environment interaction effects can be evaluated, the main effects of the environmental factor cannot be without auxiliary information.

The design of an observational study dictates what parameters can be validly estimated and whether certain forms of interaction can be evaluated. With a *cohort study* (*see Cohort Studies*) and a binary disease outcome, absolute risks (P_{GE}) are estimable and therefore relative risks or odds ratios can be estimated too. Thus, interaction can be examined in any scale; in particular, causal interactions can be examined *via* risk differences in equation (4). For a

case–control design, odds ratios are estimable and, because the case–control design is applied to rare diseases, odds ratios are close approximations to relative risks; but absolute risks are not estimable without auxiliary information [16]. Thus, examination of causal interaction using risk differences as in equation (4) appears at first impossible. Dividing equation (4) through by P_{00} , however, yields the equivalent expression:

$$(RR_{ge} - RR_{g0}) - (RR_{0e} - 1) = 0 \quad (7)$$

Consequently, to the extent that *ORs* approximate *RRs*, causal interactions can be evaluated with case–control data even though absolute risks cannot themselves be estimated. On the other hand, the case-only design and the case-parents design do not permit the evaluation of risk differences or interaction on any scale other than multiplicative (logarithmic link), unless external data are available for estimation of main effects. Others have compared and criticized study designs and methods of data analysis for gene–environment interaction [23, 24].

The development of methods for uncovering how genes and environment work together to cause disease will remain important as long as the paradigm of gene–environment interaction continues to inform biomedical research.

Geographic Disease Risk

The availability of geographically indexed health, population, and exposure data, and advances in computing, geographic information systems, and statistical methodology, have enabled the realistic investigation of spatial variation in disease risk (*see Spatial Risk Assessment*). Each of the population, exposure, and health data may have associated exact spatial and temporal information (point data), or may be available as aggregated summaries (count data). We may distinguish between four types of studies:

1. disease mapping in which the spatial distribution of risk is summarized;
2. spatial regression in which risk summaries are modeled as a function of spatially indexed covariates;
3. cluster detection (surveillance) in which early detection of “hot spots” is attempted (*see Hotspot Geoinformatics*);
4. clustering in which the “clumpiness” of cases relative to noncases is examined.

In this article, we concentrate on the first two endeavors, since often these consider risk as a function of environmental pollutants. Much greater detail on each of these topics can be found in Elliott *et al.* [1].

Disease Mapping

Disease mapping has a long history in epidemiology [2] as part of the classic triad of person/place/time. A number of statistical reviews are available [3–6] and there are numerous examples of cancer atlases [7, 8].

Usually disease mapping is carried out with aggregate count data. We describe a model for such data. Suppose the geographical region of interest is partitioned into n areas, and Y_{ij} and N_{ij} represent the number of disease cases and the population at risk in area i , $i = 1, \dots, n$, and age-gender stratum j , $j = 1, \dots, J$. The age distribution is likely to vary by area, so a map of raw risk will reflect this distribution. Often one is interested in unexplained variability in risk and hence one controls for age and gender since these are known risk factors. For a rare disease, and

letting p_{ij} be the risk in area i and age-gender stratum j , we have

$$Y_{ij} \sim \text{Poisson}(N_{ij}p_{ij}) \quad (1)$$

For nonlarge areas in particular, the data will not be abundant enough to reliably estimate the risk in each area for each age and gender category, i.e. each p_{ij} . Hence it is usual to assume proportionality of risk, i.e., $p_{ij} = \theta_i \times q_j$, where q_j are a set of reference risks (perhaps taken from a larger region [9]), and θ_i is the *relative risk* (ratio of risks) (*see Absolute Risk Reduction*) associated with area i ; this model assumes that the effect of living in area i is constant across stratum (an assumption that should be checked in applications). Then

$$Y_i = \sum_{j=1}^J Y_{ij} \sim \text{Poisson}(E_i \theta_i) \quad (2)$$

where $E_i = \sum_{j=1}^J N_{ij}q_j$, are the *expected numbers*. The use of expected numbers is known as *indirect standardization*. The standardized mortality/morbidity ratio (SMR) is the estimate $\hat{\theta}_i = Y_i/E_i$. The variance of the estimator is $\text{var}(\text{SMR}_i) = \text{SMR}_i/E_i$, which will be large if E_i is small, which occurs when the populations are small.

To illustrate, we calculate SMRs using lung cancer mortality data over the years 1998–2002 in the state of Minnesota. These data are more fully described in [10]. The observed counts range between 14 and 3012 across counties, with median 71. Expected numbers are available, with adjustment for age and gender, and range between 16.8 and 2818. Figure 1 provides an SMR map. The SMRs range between 0.58 and 1.38, which is a relatively narrow range because the expected numbers are quite large here. The most easterly county, Cook county, has an SMR of 1.22, but an expected number of 20.5, suggesting that the high SMR may reflect sampling variability.

More reliable estimates can be obtained using random-effects models [11, 12] that use the data from all areas to provide more reliable estimates in each of the constituent areas. A popular log-linear model assumes

$$\log \theta_i = \mu + x_i \beta + U_i + V_i \quad (3)$$

where U_i and V_i are random effects with and without spatial structure, x_i are covariates associated with

Figure 1 (a) Lung cancer standardized mortality ratios (SMRs) and (b) average radon in 87 counties of Minnesota

area i , and β is the vector of log relative risks associated with these covariates. The V_i terms give global smoothing to the overall mean, the U_i allow local smoothing so that “close-by” areas are likely to be similar, and $x_i\beta$ models similarity between areas with similar covariate values. Details of specific spatial models, including neighborhood schemes, and computational strategies are available elsewhere [6, 12]. Once reliable estimates of the relative risk are available, these may be used for public health purposes (for example, to decide on which areas to promote screening campaigns), or they may be compared with maps of environmental exposures in order to investigate the association between risk and exposure.

Spatial Regression

The formal comparison with risk and exposure is carried out using so-called ecological correlation studies, and numerous such studies have been reported [13]. Exposures may be directly measured in air, water, or soil, or be indirect surrogates such as latitude as a surrogate for exposure to sunlight, distance from a point source of risk such as an incinerator [14], or a foundry [15], or a line source such as a road.

With aggregate count data, model (3) may also be used in the context of spatial regression, though now β is of primary interest and one must be aware of ecological bias that occurs when individual-level inference is attempted from aggregated data and arises

due to within-area variability in exposures and confounders [16–18]. We illustrate by returning to the Minnesota example but now assume that the aim is to estimate the association between risk of lung cancer mortality and residential radon. Radon (*see Radon*) is a naturally occurring radioactive gas present in rocks and soil. Extensive epidemiological studies on highly exposed groups, such as underground miners, consistently indicate a substantially increased risk of lung cancer at high concentrations of radon [19]. However, extrapolation to lower doses, typical of those found in residential homes, is more controversial. Many studies that address residential radon have been ecological in design, but their usefulness is debated, in part owing to the problems of interpretation in the presence of ecological bias [20]. As a result, conclusions from such studies are conflicting, with ecological studies often displaying a negative association between radon and lung cancer. We utilize radon measurements in individual homes in Minnesota collected by the environmental protection agency (EPA) and Minnesota Department of Health in 1987. The sample sizes associated with the radon measurements, by county, are very small, ranging between 1 and 122 (median 5), with two counties having 0 individual radon measurements. Figure 1(b) displays average radon by county. Comparison with the SMRs in Figure 1(a) seems to indicate a negative association (there is a northeast to southwest decreasing trend in the SMRs, and the opposite in radon). Figure 2 shows the SMRs versus average radon, and confirms a clear negative association, indicating a protective

Figure 2 SMRs versus mean radon levels (pCi l^{-1}), along with fitted log-linear model

effect. We assume the model

$$E[Y_i] = E_i \exp(\mu + \beta x_i), \text{var}(Y_i) = \kappa \times E[Y_i] \quad (4)$$

where x_i is the average radon in area i , and κ allows for overdispersion. We fit this model using quasi likelihood [21], and obtain $\hat{\beta} = -0.036$ (with a standard error of 0.0090) to give a highly significant area-level relative risk of $\exp(-0.036) = 0.96$, indicating a 4% drop in risk for every 1 unit increase in radon. For these data, $\hat{\kappa} = 2.8$, so there is a large degree of excess-Poisson variability (note that this model does not account for residual dependence in the counts). The fitted curve in Figure 2 corresponds to the fit of this model. For a more thorough analysis of the radon example that addresses ecological bias, see [10]. Here we briefly mention some problems with the above analysis. Smoking is a confounder that we have not controlled for, and there is within-area variability in radon exposure that can lead to pure specification bias that arises under the aggregation of a nonlinear individual-level model. The only way to overcome ecological bias is to supplement the ecological information with individual-level data, and this is the subject of much current work [18, 22–24]. In conclusion, associations estimated at the aggregate level should be viewed with caution owing to the potential for ecological bias, but ecological data can offer clues to etiology, and add to the totality of evidence of a given relationship (see **Ecological Risk Assessment**).

In the above, we have considered spatial regression with count data. With point data a similar approach is available with a Bernoulli likelihood and a logistic, rather than log, link function. There are no problems of ecological bias with individual-level data, but the spatial aspect should still be considered. This may be less of a problem if individual-level information on confounders is gathered, as this will reduce residual dependence, since it is unmeasured variables that contribute to this dependence (along with errors in the data that have spatial structure, and other sources of model misspecification [25]). It is usual for aggregate data to provide (hypothetically) complete geographical coverage, but with point data one must carefully examine the data collection scheme since it may have spatial structure; in particular cluster sampling may have been carried out. In these cases, spatial dependence reflects not only inherent variability but also that arising from the sampling scheme.

We finally note the potential for “confounding by location”. Often risk and exposure surfaces have local and global spatial structure, so when one progresses from a model with no modeling of spatial dependence to one with spatial effects, one may see large changes in the regression coefficients of interest. This occurs because the initial coefficient may reflect not only the exposure of interest but also other variables associated with risk that are correlated with the exposure surface. This is a complex issue [26, 27] since overadjustment for spatial location is also possible. The ideal scenario is when one has good data on confounders, since in this case any adjustment for spatial dependence should not change estimated associations too drastically.

Conclusions

A major weakness of geographical analyses investigating the association between environmental pollutants and risk is the inaccuracy of the exposure assessment. Modeling of concentration surface has become more common (for a state-of-the-art treatment, see Le and Zidek [28]), but care is required in the use of such methods since inaccuracies in the modeled surface (which are often based on sparse monitor data) may introduce greater bias than that present in simple methods that, for example, use the nearest monitor for exposure assessment [29].

Global Warming

The global average annual temperature of the Earth's surface has increased by as much as 0.7°C since the late nineteenth century, with significant warming in the last 50 years. The scientific consensus, best represented in this matter by the Intergovernmental Panel on Climate Change (IPCC), is that a significant portion of this increase, and most of the warming in the last 50 years, is very likely (i.e., with probability greater than 0.9 according to the IPCC definition of the phrase) attributable to human activities – most notably the burning of fossil fuels – leading to increased concentrations of greenhouse gases (GHGs) in the atmosphere. Further, the consensus is that a larger future warming is in store in the absence of significant curbing of GHG emissions, with 2°C additional warming being generally accepted as a lower bound estimate of the expected global warming at the end of the twenty-first century under so-called business as usual emission scenarios.

Of course, in the absence of our atmosphere, and its natural greenhouse effect, the temperature of Earth would soar during the day and fall dramatically at night. The entire amount of solar energy incoming on the surface of our planet would be immediately reflected back. The presence of GHGs in our atmosphere (CO_2 , methane, water vapor, and ozone being the main constituents), able to “trap” part of the radiation that the Earth's surface reflects back, keeps our planet inhabitable. However, human activities are dumping enormous quantities of GHGs in the atmosphere every day, mainly through the burning of fossil fuels. There is no doubt that the increase in the CO_2 concentrations in the atmosphere comes from human activities, since the origin of its molecules can be traced exactly, owing to a difference in the isotopes of naturally produced rather than man-produced gases. The higher concentrations of these gases make the planet increasingly warmer. There are positive feedbacks superimposed on this straightforward mechanism (e.g., the melting of ice caps, because of the warmer atmospheric temperature, uncovers water, which absorbs more incoming radiation than the reflective surface of ice, further warming the sea surface temperatures of northern regions, and melting more ice). There are countereffects produced in part by the same industrial activities responsible for the production of GHGs, i.e., aerosols (small

particles suspended in the atmosphere, which actually consist in large measure of natural dusts, produced by volcanic eruptions and dust storms), which act as screens, keeping incoming radiation from penetrating the atmosphere. Aerosols, however, are short-lived agents, and not as well mixed as GHGs, making their cooling effect more transitory, and geographically less homogeneous (and thus more difficult to predict). Complicating the detection of warming and human influences is the natural variability of the system, owing to low-frequency signals that impact temperatures even in their global average, like the El Niño Southern Oscillation and the North Atlantic Oscillation. The solar radiation also goes through natural phases, creating warmer and cooler multiyear phases, which have however been quantified as insufficient to explain the warming observed in the last decades. A source of uncertainty in the exact quantification of future global warming is the effect of clouds. Warmer climates mean larger amounts of water vapor in the air, so it is to be expected that changes in the formation of clouds are in store as well, with GHGs increasing. The formation of clouds is, however, an extremely complex process, which is impossible to represent explicitly in the current generation of climate models because of limited spatial resolution, and may have contrasting effects on the climate system: high clouds may screen incoming radiation with a cooling effect and low clouds may trap a larger fraction of the reflected radiation, keeping the surface of the Earth warmer. Even in the presence of all these complicating factors, analysis of the observed records and comparison with idealized experiments has quantified evidence that the warming observed so far is inconsistent with estimates of natural variability, and natural change in forcings owing to solar or other low-frequency modes of variability. The detection of an “unnatural” warming and its attribution to human causes is being performed for increasingly more variables, and phenomena that are increasingly finer in scale. For example, it is a strong result for global average temperature [1], but it has also been proved for regional temperature changes [2], and very recently for sea surface temperatures in the cyclogenesis regions of the Atlantic and the Pacific [3].

Global average increases in temperature are just an aggregation of heterogeneous regional climatic changes that are very likely to affect societies and ecosystems in adverse rather than beneficial ways. Climate models and scientific understanding of

climate processes project more frequent and intense extreme events and do not rule out the possibility of exceeding systemic thresholds for climate variables causing abrupt changes, with potentially much more dangerous consequences than simple gradual shifts in the makeup of regional climatologies. Associated climatic changes and economic, biological, and health-related impacts are then to be expected, ranging from changes in agricultural yields and forced abandonment and geographical shifts of crops to disruption of ecosystems and from depletion of water resources to easier spread of vector-borne diseases.

If the qualitative nature of the problem represented by global warming is generally agreed upon by a large share of the scientific, policy-making, and stakeholders' communities, a quantification of the risks associated with the above story line is far from straightforward.

There exist considerable uncertainties, both in terms of limits to predicting future changes in the drivers of GHG emissions (population, economic growth, etc.) and incomplete scientific understanding of the response of the climate system to those emissions, and in terms of intrinsic randomness or unpredictability of the processes involved. From the size of the changes to be expected to their timing and from the significance of their impacts to the costs of adaptation and mitigation strategies, every link of the chain from GHG emissions to impacts to the effects of response strategies is affected by uncertainties. The quantification of these uncertainties using distributions of probability cannot often rely on engineering-like assessments, i.e., cannot draw on an exactly replicable experimental setting or long records of observations from stationary processes. Rather, subjective choices based on expert knowledge are often necessary in the statistical modeling of the random quantities at stake, opening the way to debates and to the formation of an additional layer of uncertainty, a meta-uncertainty, that is, over the distributions of probability so derived.

In this article we will attempt to characterize the main sources and characteristics of these uncertainties, together with the most rigorous efforts currently documented in the peer reviewed literature to quantify them and incorporate them into risk analyses.

We describe in the section titled "Uncertainties in Climate Modeling" uncertainties in modeling of the climate system and their characterization and quantification through single-model and ensemble

experiments. In the section titled "Uncertainties from Boundary Conditions: Future Scenarios of Emissions" we address uncertainties in the development of future emission scenarios, recognized as the principal driving force of climatic change. The section titled "Approaches to Risk Assessment and Risk Management" describes methods and results from state-of-the-art modeling strategies adopted by impacts science and policy analysis in the arena of risk assessment and risk management. On account of the availability of a number of comprehensive reviews of climate change science, impacts, adaptation, and mitigation studies, we choose to limit the list of references to the works that we explicitly cite in this article's discussion. In the section titled "Pointers to Sources of Information in Climate Change Science, Impacts, Mitigation, and Adaptation", we list the major sources of information available for overviews or more in-depth study of climate change.

Pointers to Sources of Information in Climate Change Science, Impacts, Mitigation, and Adaptation

Every 5–6 years since 1990, the IPCC, a United Nations (UN)/World Meteorological Organization (WMO)-sponsored international organization, has published an assessment report, compiling a critical summary of the state of research on the science of climate change, its impacts and the efforts on the front of adaptation strategies, plus economic-driven studies of mitigation policies.

The last published report at the time of this writing is the third, available in its entirety, together with the two previous reports, at <http://www.ipcc.ch>. The next report will be published in the first months of 2007, and will be available through the same website.

Within the report, especially relevant to the discussion in this article, are the chapters by Working Group 1 in "The physical science basis" on "Understanding and Attributing Climate Change" (Hegerl and Zwiers coordinating lead authors), "Global Climate Projections" (Meehl and Stocker), and "Regional Climate Projections" (Christensen and Hewitson) and the literature they cite.

Amongst the chapters by Working Group 2, in "Impacts, Adaptation and Vulnerability", we have drawn on the discussion in "New assessment methodologies and the characterization of

future conditions” (Carter, Lu, and Jones) and in “Assessing key vulnerabilities and the risk from climate change” (Patwardhan, Semenov, and Schneider) and the literature assessed therein. A Special Report on Emission Scenarios (SRES) is available through the IPCC website, and addresses the construction of the GHG emission scenarios on the basis of story lines of future economic and social world development. The United States National Assessment report was produced in 2000, sponsored by the United States Global Change Research Program, a government entity. It is available at <http://www.usgcrp.gov/usgcrp/nacc/default.htm>.

In October 2006, a review of climate change science and impacts was compiled for the UK government by Sir Nicholas Stern. Setting it apart from the IPCC reports and other national assessment reports is the economic focus of this synthesis report, where explicit figures of projected loss in global GDP and detailed scenarios of specific impacts and their costs are laid out, and prescriptions like environmental taxes are put forward. The entire report is available at http://www.hm-treasury.gov.uk/independent_reviews/stern_review_economics_climate_change/sternreview_index.cfm.

On a lighter note, “The rough guide to climate change” has been recently published. In this book, Robert Henson gives a complete but very accessible picture of the symptoms, the science, the debates, and the solutions of this issue [4]. In all these review texts, extensive bibliographies are available.

Uncertainties in Climate Modeling

Similar to what happens for day-to-day weather forecasts, projections of future climate are based on numerical model experiments that resolve or parameterize the processes relevant for the forecast time scale of interest, in our case, decades to centuries.

Weather and climate models are based on the representation of the laws of fluid dynamics that govern weather processes. They approximate these laws at a finite set of points discretizing the three physical dimensions of Earth and at a sequence of finite time steps, usually at increments on the order of a few minutes, for length of simulations ranging from hours (for weather models) to centuries (for climate models).

The relevant sources of uncertainty in constructing and applying climate models are classifiable into boundary condition, parameter, and structural

uncertainties. Initial conditions are often dismissed as a source of uncertainty in climate projections since the results from model runs are usually averaged over decades and over ensemble members (i.e., over comparable simulations from the same model under different initial conditions, or from different models).

An uncertainty from boundary conditions arises because the model experiments, which are otherwise self-contained, rely on inputs that represent external influences, in the form of estimates of solar and other natural forcings or, in an atmosphere-only models, sea surface temperatures, and sea ice cover. For our discussion, the most relevant external input, and one that is fraught with uncertainties, is the change in atmospheric concentrations of GHGs over the course of the future simulated time, which we will discuss in detail in the section titled “Uncertainties from Boundary Conditions: Future Scenarios of Emissions”.

On account of limited computing power, climate processes and their interactions can be represented in computer models only up to a certain space and time scale (the two being naturally linked to each other). The current state-of-the-art atmosphere-ocean coupled climate models have spatial resolutions on the order of a 100 km in the horizontal dimension, and about 1000 m in the vertical dimension. The effects on these scales of processes living at finer scales must be parameterized with bulk formulas that depend on large-scale variables available in the model. One such parameter is, for example, the percentage of cloud cover within a model’s grid cell. This percentage depends on a number of other quantities and processes that are simulated explicitly or implicitly by the model, and is responsible for feedbacks on the large-scale quantities. However, the formation of clouds is an extremely complex process that cannot be simply measured empirically as a function of other large-scale observable (and/or representable in a model) quantities. Thus the choice of the parameters controlling the “formation of clouds” within the model cells has to be dictated by a mixture of expert knowledge and goodness of fit arguments, based on actual model runs and a number of diagnostic measures, often conflicting with one another. Of late, parameter uncertainties have started to be systematically explored and quantified by so-called perturbed physics ensembles (PPEs), sets of simulations with a single model but different choices for various parameters. In fact, many studies that have attempted to quantify climate change in a probabilistic sense have

taken this approach. However, the PPE approach is hampered by the limited interpretability of many of the parameterization choices in complex climate models. Only for a limited number of the parameters, in fact, can either empirical evidence or scientific understanding dictate sensible ranges of variation for the sensitivity analysis, and often the tweaking of parameters takes place without considering dependencies among them.

The third type of uncertainty is introduced at a fundamental level by the choices of model design and development. From basic structural features of a particular model, like type of grid, resolution, and numerical truncation, to physical aspects, like the choice of representing land-use change or not and of making it interactive or not, there are sources of variation across model output that cannot be captured by parameter perturbations, and are thought to introduce a degree of intermodel variability of larger magnitude than any PPE experiment is able to explore. The analysis of multimodel ensembles has sought to tackle this dimension of uncertainty by taking advantage of so-called ensembles of opportunity, i.e., collecting the results of standard experiments performed by different models under comparable setup.

Even if the future projections of models cannot be validated for decades to come, there are many measurements available, of past and current records, which permit the validation of the fundamental abilities of climate models to simulate the Earth's climate. Observations of hundreds of quantities on the surface, in the vertical dimension of the atmosphere, and from the depth of the oceans are used to verify the ability of these models to replicate the characteristics of current climate (from the beginning of the instrumental records), not only in mean values but also in terms of simulated variabilities at a whole spectrum of frequencies. Paleoclimate proxies (tree rings, ice cores, corals, and sediments) are used to validate the century-scale oscillations of the simulations. Experiments that simulate volcanic eruptions test the "reaction time" of the simulated system, since observations track the sudden dip in globally average temperatures and the subsequent recovery, occasioned by major volcanic eruption in the tropical zones. Long "unforced" simulations, worth hundreds of years' time are run to test the self-consistency and stationarity of so-called control climate, i.e., time series of variables produced by simply allowing the internal variability of the system play out, without

natural (e.g., solar) or anthropogenic (e.g., changes in GHGs concentrations) forcings imposed. Thus, climate model performance can be validated under many metrics and diagnostics, and state-of-the-art models are expected to pass many tests, even if it is true that no climate model performs perfectly under the whole spectrum of measures, and different models have different strengths and weaknesses.

Perturbed Physics Ensemble Experiments and Their Analysis

Given enough computational capacity, the PPE approach is a fairly straightforward enterprise: parameters are perturbed within sensible ranges and the results of model runs, given a particular setting, are validated by observations. The experiments that deliver a better performance with respect to diagnostics of choice (several observed and modeled quantities are often tested against each other) are weighted more than those that generated less realistic results. Future climate parameters of interest are collected from all the perturbation experiments and their empirical probability distributions are derived and weighted on the basis of the results of the validation step. Recent studies have used these results to produce probability density functions (PDFs) of quantities like equilibrium climate sensitivity (defined as the amount of long-term global average warming at the time of associated with a doubling of CO₂ concentrations after the climate system reaches a new equilibrium, under the hypothesis that the GHG concentrations are maintained at that fixed level); global average warming during a transient simulation (i.e., without the requirement that the climate system reach a new equilibrium, in the presence of continuing external forcing); the present-day magnitude of the aerosol forcing, and various other projections. We should note here that the computational cost of PPEs has made it unfeasible so far to run large perturbation experiments of fully coupled climate models, which are the only direct means to derive future projections of climate change at regional scales. Either simple models [5], intermediate complexity models [6], or atmosphere-only models coupled to a simplified ocean module [7, 8] have been used. Thus, in most cases, the uncertainties quantified through PPE studies pertain to global average quantities or equilibrium rather than transient quantities, and are not straightforwardly usable in most risk assessment analyses for the purpose of policy making, which

demand regional quantities as input. An additional statistical step needs to be taken in order to link projections from PPEs to transient future changes at regional scales. This has been worked out, for example, through the assumption that the geographical patterns of change, once standardized per unit of global warming, are stable and constant across time. This method, called *simple pattern scaling*, has been tested and validated, and appears to produce accurate projections for average temperature changes and – in a less robust way, at least for increasingly finer regional changes – for average precipitation, but is less defensible if projections are sought for other climate variables (e.g., winds, sea level rise), and quantities other than averages (e.g., extremes). Unfortunately, these are often the most relevant kind of projections for risk assessment.

Work to link results from PPE experiments to runs by fully coupled General Circulation Models (GCMs) continues [9]. This area is, in fact, making use of interesting statistical modeling, for example, in order to construct “emulators” able to represent climate model output over a large space of parameters’ ranges, in the absence of actual model experiments filling in the parameter space in its entirety [10]. We need to point out that in order to explore the full range of uncertainties and for making sure that the results of this type of analysis are not dependent on the particular model used in the PPE experiments, an ensemble of different models should be considered. Unfortunately, given the computational cost of PPE approaches, only the Hadley center model, from the UK met office, has performed systematic experiments of this kind [11]. Other such efforts should be encouraged, since the resolution of the major model uncertainties has to rely on both “between model” and “within model” ensemble analyses.

Structural Uncertainty Exploration and the Analysis of Multimodel Ensembles

Results from different fields of application (e.g., public health, agriculture, and hydrology) have shown that combining models generally increases the skill, reliability, and consistency of model forecasts. In weather and climate forecast studies (especially seasonal forecasts for the latter category, where verification is more straightforward) multimodel ensembles are generally found to be better than single-model forecasts, particularly if an aggregated performance measure over many diagnostics is considered.

Multimodel ensembles are defined in these studies as a set of model simulations from structurally different models, where one or more initial condition ensembles are available from each model (if more initial conditions for each model are available the experiments are often said to constitute a super ensemble). On account of several international efforts, most importantly the IPCC-driven activities, in preparation for its multiannual assessment reports, multimodel ensembles are becoming increasingly available in the climate change analysis field as well. These joint experiments are usually performed within a systematic framework in support of model diagnosis, validation, and intercomparison. Table 1 lists the models that have contributed to the latest IPCC-AR4 and the corresponding modeling centers where the models are developed.

There are obviously different ways to combine models, and controversies exist regarding which is best, even in applications where skill or performance can be calculated by comparing model predictions to observations. The problem is rendered more challenging for climate projections, where no simple verification is attainable.

Multimodel projections for long-term climate change were used in reports of the IPCC, in the form of unweighted multimodel means, and were thought of as better best-guess estimates than the projections of single models. The underlying assumption was and is, of course, that the independent development of models makes their structural errors random and likely to cancel one another in an average. In this context, the only measure of uncertainty associated with the multimodel means was an intermodel deviation measure, consisting of a simple standard deviation measure often calculated on the basis of as few as seven to nine models.

Probabilistic projections based on multimodel ensembles are rather new in the literature and are based on a variety of statistical methods. In 1997, Raisanen [12] for the first time advocated the need for a quantitative model comparison and the importance of intermodel agreement in assigning confidence to the forecasts of different models. A few years later, in 2001, Raisanen and Palmer [13] published the first article to propose a probabilistic view of climate change on the basis of multimodel experiments as an alternative to the simple estimate of the average of the models. On the basis of 17 models, probabilities of threshold events such as “the warming at the

time of doubled CO_2 will be greater than $1^\circ\text{C}''$ were computed as the fraction of models that simulated such event. These probabilities were computed at the grid-point level and also averaged over the entire model grid to obtain global mean probabilities. The authors used cross-validation to test the skill of the forecast so derived, for many different events and forecast periods. They also showed how probabilistic information may be used in a decision theory framework, where a cost–benefit analysis of initiating some action may have different outcomes depending on the probability distribution of the uncertain event, from which protection is sought. Naturally, in their final discussion, the authors highlighted the importance of adopting a probabilistic framework in climate change projections, and wished it became an “established part of the analysis of ensemble integrations of future climate”. The same authors applied the same procedure to forecasts of extreme events [14].

In 2003, Giorgi and Mearns published a significantly different approach to the computation of threshold events, as a follow-up to their method

described in a first paper the year before [15, 16], by proposing the first weighted average of models, based on model performance and model agreement. Their reliability ensemble average (REA) approach rewards models with small bias and projections that agree with the ensemble “consensus”, and discount models that perform poorly in replicating observed climate and that appear as outliers with respect to the ensemble’s central tendency. This is achieved by defining model-specific weights as

$$R_i = \left\{ \left[\min \left\{ 1, \frac{\varepsilon_T}{\text{abs}(B_{T,i})} \right\} \right]^m \left[\min \left\{ 1, \frac{\varepsilon_T}{\text{abs}(D_{T,i})} \right\} \right]^n \right\}^{[1/(m \times n)]} \quad (1)$$

where the subscript i indexes the different models of the ensemble. In equation (1) the term ε_T is a measure of natural variability of, say, average seasonal temperature in a given region; $B_{T,i}$ represents the bias (the discrepancy between a model simulation and observations) in the simulation of

temperature in the region by model i , for a period for which observations are available and that constitutes the baseline with respect to which “change” is defined. The term $D_{T,i}$ represents a measure of distance of the i th projection of temperature change from the consensus estimate. The weights R_i are used to construct a weighted average of model projections for the future climate mean, with standard error also computed from the weights. Using the form (1) the weights cannot be computed upfront but are estimated by an iterative procedure, starting with a consensus estimate that is a simple average and iterating to convergence. It is easy to show that if the form of $D_{T,i}$ is an Lp norm the optimal solution to the estimation problem is $\Delta\tilde{T}$ that minimizes $\sum_i C_i |\Delta T_i - \Delta\tilde{T}|^q$, where C_i is the part of the weight that does not depend on $D_{T,i}$, and q is the function of p . In [15, 16] the authors chose m and n such that q is equal to one, making the result of the estimation amount to the choice of a robust measure of location, the weighted median of the observations. Interestingly, this fact went unnoticed by the authors of the REA approach and was recognized in [17]. Besides the innovative step of considering two criteria in the formal combination of the ensemble projections, the focus on regional analyses made the methods more directly relevant for impact studies and decision making. However, the authors stopped short of applying probability distributions to actual decision-making contexts.

The REA approach motivated the work in [18] and [19]. A Bayesian statistical model (*see Bayesian Statistics in Quantitative Risk Assessment*) was proposed as the basis for any final estimate of climate change probabilities. The Bayesian analysis treats the unknown quantities of interest (current and future climate signals, whose estimated difference is equivalent to $\Delta\tilde{T}$ in [15, 16], and model reliabilities that serve the same function as the weights R_i , above) as random variables with appropriate prior distributions. Assumptions on the statistical distribution of the data (models’ output and observations) as a function of the unknown parameters (the likelihood) are combined through *Bayes’ theorem* (*see Bayes’ Theorem and Updating of Belief*) to derive posterior distributions of all the uncertain quantities of interests, including the climate change signal. The likelihood model assumes that the current and future temperature simulations by model i , respectively, X_i and Y_i , are centered on the true climate signals, μ (for current

average temperature) and ν (for future average temperature) with a precision that is model-specific, as in:

$$X_i \sim N(\mu; \lambda_i)$$

$$Y_i|X_i \sim N(\nu + \beta(X_i - \mu); \theta\lambda_i) \quad (2)$$

The Gaussian assumption is motivated by the fact that X ’s and Y ’s are large regional and seasonal averages, and it is believed that the models will aim at approximating the true climate with errors that are normally distributed, each model with its own specific degree of precision. In equation (2) the linear term in the mean of Y_i serves the function of allowing for correlation between current and future simulated temperature by the same model. The parameter θ introduces a deflation/inflation factor in the precision of the models when comparing the accuracy of current-day simulations and future simulations. The λ_i terms represent the model-specific precisions. The unknown parameters λ_i , μ , ν , θ , and β are all given improper or highly dispersed prior distributions to represent a state of prior ignorance. The distributional form of the priors is conjugate to the likelihood model and the joint posterior distributions for all the parameters can be easily derived by Markov chain Monte carlo simulation and its marginal for the difference $\nu - \mu$ can be straightforwardly evaluated to represent the best guess at future temperature change and its uncertainty. The simple model in equation (2) is applied to single subcontinental size regional averages of temperature or precipitation. A more complex model introduced region-specific parameters in the mean and variance structure of the Gaussian likelihood, to treat more than one region at a time, thus borrowing information across space in the estimate of the model-specific and common parameters [20].

The papers [18, 19] were the first to propose a formal statistical treatment of the data available that produced regional probabilistic projections of temperature and precipitation change. The regional perspective was also adopted by Greene *et al.* [21]. In this paper, formal statistical models are adapted from the seasonal forecasting methodology to long-term future projections, basically fitting a linear model between observed (as regressand) and modeled temperatures (as regressors) from the ensemble of models. The probabilistic nature of the results is here too a natural product of adopting a Bayesian approach, with multivariate Gaussian priors for the coefficients of the regression. After determining the

posterior for the coefficients, the same are applied to the future temperatures simulated by the same models, and PDFs of temperature change at large regional scales are derived.

The methods described so far all used large regional averages of model output, producing probabilistic projections at the subcontinental scale.

Furrer *et al.* [22] attacked the statistical modeling of GCM output at the grid-point scale, using spatial statistics techniques (*see Spatial Risk Assessment*) and thus producing probabilistic projections able to jointly quantify the uncertainty over the global grid. They do so by modeling geographical features of the fields of temperature and precipitation change at varying degrees of smoothness, accounting for the spatial correlation between locations as a function of their distance. They use Gaussian random fields to model the residual terms after projecting larger scale features over a set of basic functions comprising spherical harmonics, land-ocean contrasts, and observed mean fields.

Perhaps better suited to actual impacts assessment and thus a formal risk analysis, some studies have forgone the general approach and focused on projections for specific areas and impact type. For example, Benestad [23] used statistical downscaling of a multimodel ensemble to derive probabilistic scenarios at fine resolution over northern Europe. Luo *et al.* [24] analyzed impacts over Australian wheat production by using Monte Carlo techniques to explore the range of uncertainties as quantified by the multimodel ensemble, besides addressing other sources of uncertainty like future emission scenarios.

A Single-Model Approach at Quantifying Future Warming Uncertainty

An alternative approach has developed from a paper by Myles Allen *et al.* [25] and characterizes the uncertainty in climate change projections on the basis of results from a single model. A regression performed between observed global trends and model simulated global trends (where the latter come from separate experiments by the same model using selective subsets of the forcings known to have influenced the observed temperature trends: natural, GHGs, sulfate aerosols) allows to gauge the model's accuracy in reproducing the observed trends, and the scaling needed on the coefficients of the forcings to make the climate simulations agree with observed changes.

The model is that of a simple linear regression:

$$y = \sum_{i=1}^m (x_i - v_i) \beta_i + v_0 \quad (3)$$

where the observations y are regressed over modeled response patterns (x_i) to different forcings applied separately within the model's experimental setting. Here the y 's and x 's are derived from a time series of global fields produced by the model runs through a principal component analysis, able to extract the main spatial patterns of variability from the results of each experiment's simulations and from the observed records. The response-specific error terms in equation (3), v_i , derive from the natural variability intrinsic to model runs that introduces noise in the spatial patterns.

Then, under the assumption that the underestimate or overestimate of the effect of the specific forcings within the current climate simulations remains the same in the future runs of the model, the scaling factors β_i are applied to the model's future projections, together with their estimated uncertainty:

$$y^{\text{for}} = \sum_{i=1}^m (x_i^{\text{for}} - v_i^{\text{for}}) \beta_i + v_0^{\text{for}} \quad (4)$$

where the x 's are now model predictions under future scenarios of anthropogenic and natural forcings. A distribution for y^{for} can be derived as a function of distributions estimated for the scaling factors. On account of the need of a strong signal-to-noise ratio when detecting warming and attributing it to anthropogenic causes through the estimate of equation (3), this analysis has been mainly limited to global temperature change, and only recently the same approach has been attempted at continental scales. As was expected, the lack of a strong signal in the anthropogenic component of the historic trends at regional scales, and the consequent larger uncertainty in the estimate of the corresponding scaling coefficients produces extremely large uncertainty bounds for future projections. This problem would be exacerbated if the same analysis were applied to other climate variables (e.g., precipitation change).

Uncertainties from Boundary Conditions: Future Scenarios of Emissions

The analyses described in the section titled "Uncertainties in Climate Modeling" are concerned with the quantification of the uncertainty in future projections stemming from natural variability, (which

would confound changes in climate statistics even in the absence of external forcings) and from model uncertainty (caused by our limited understanding and capacity for representation of climate processes). A third important source of uncertainty derives from not knowing what future emissions will be like. Thus, in most cases the analysis of model output is conducted conditionally on a specified scenario of future emissions, and a range of different scenarios is explored in order to bracket as large a spectrum of “possible futures” as resources permit.

The compilation of future scenarios is in itself a complex matter, with the need to take into account a number of social, political, and economic factors: population growth will determine the consumption of natural resources, economic development will require energy, and technical and scientific progress will shape the way in which alternative (clean and renewable) sources of energy will take the place of fossil fuels. The level of international collaboration will determine how advances in carrying out sustainable development will spread around the world, especially in those countries undergoing intense economic development like China and India. IPCC, in the late 1990s, commissioned a SRES charged with developing story lines of possible future world development, and translating these into emission scenarios. Six scenario groups were developed, covering wide and overlapping emission ranges. These ranges become wider over time to account for long-term uncertainties in the driving forces (different socioeconomic developments, energy sources availability, degrees of technological innovation, etc.). Some SRES scenarios show changes in the sign of trends (i.e., initial emission increases followed by decreases), and cross paths (i.e., initially emissions are higher in one scenario, but later emissions are higher in another). The range of total carbon emissions at the end of the twenty-first century goes from 770 to 2540 GtC. Emissions from land-use changes are also considered, together with emissions of hydrofluorocarbons and sulfur. As we mentioned, uncertainties in the depiction of future emissions are complicated by the interplay of natural, technological, and social aspects and the IPCC report explicitly acknowledged that: “Similar future GHG emissions can result from very different socioeconomic developments, and similar developments of driving forces can result in different future emissions. Uncertainties in the future developments of key emission driving forces create large uncertainties

in future emissions, even within the same socioeconomic development paths. Therefore, emissions from each scenario family overlap substantially with emissions from other scenario families.” There is no easily identifiable driving force, not even one that is itself an integrator of a complex set of factors, like income growth, that has a determinant influence on the size and rate of GHG emissions.

Of course, where the analysis of most climate quantities is concerned, different scenarios cause significant differences in model output, especially when evaluating long-term future changes. These differences translate not only in different intensities of the projected changes (this being the case for average temperature changes whose behavior shows direct proportionality to the concentrations of GHGs), but also in the regional patterns by which these changes are predicted to take place. Unfortunately, the range of uncertainty determined by different scenarios may be as large as the one determined by structural uncertainty, or uncertainty in climate response to external forcings. Thus, a quantitative risk assessment of the impacts of future changes that seeks to encompass the complete range of uncertainty would require the – uncomfortable for most – attribution of probabilities to future scenarios.

Some advocates of a fully probabilistic approach to climate change have proposed approaching the problem of assigning probabilities to the different future scenarios in a necessarily subjective (Bayesian) way. This proposition has encountered strong resistance, however, and so far the only attempts at integrating the uncertainty from alternative scenarios into the final range of probabilistic projections have assumed equal probability for the different alternative [5, 16]. This “default” approach has not avoided sharp critiques, fueled by the fact that some of the scenarios have been derived heuristically rather than through explicit economic and social dynamics’ modeling, and are thus thought of being considerably less likely than others. Alternatively, impact studies have chosen to develop their analysis conditionally on a given (set of) SRES scenarios, determining consequences for each separately and – in the best examples of this approach – trying to at least ensure the representation of the outer envelope of possible future paths. Among the SRES scenarios, four have been extensively utilized in computer experiments, and the results of these experiments are thought of as being representative of a large range of the uncertainty linked to

future GHGs emissions. They are identified by the labels B1, A1B, A2, and A1FI. In an appendix, we give a more detailed description of the story lines behind them.

Approaches to Risk Assessment and Risk Management

The challenges offered to risk assessment by climatic change have been summarized recently in the Stern report as existing along two dimensions. The first has to do with the uncertainties described in the previous sections of this paper: depending on the modeling uncertainties, different climate variables have very different levels of uncertainties attached to their projections, with some variables at some scales being better “predictable” in a probabilistic sense than others. If it is relatively easier to talk about global average temperature change, especially for shorter time frames before the effects of different emission scenarios start to be felt, it is much more challenging to predict temperature at smaller regional scales, and to do so independently of scenarios, if the horizon becomes longer (for example, if predictions are sought for the end of the twenty-first century as opposed to middle of the century). Even more challenging are quantitative, probabilistic predictions of other parameters (starting from precipitation) and other aspects of the climate system (e.g., extremes). The uncertainty grows further when one tackles regime changes triggered by exceedance of systemic thresholds.

The second dimension has to do with the quantification of the costs associated with impacts and policy measures to prevent them. It is relatively easy to assess market-determined costs, but often the victims of climate change are nonmarket entities (like biodiversity or human health), and the brunt of the costs are to be borne by future generations. The magnitude of the discounting rate that is appropriate when considering decisions regarding mitigation of future climate impacts involves considerations of inter-generational equity and has been matter of significant debate. Also, the actual impacts taking place in the future are dependent on socially contingent hypotheses, leaving the possibility open of positive and negative feedbacks along the way, dynamic adjustments, and socially and politically driven changes that may influence the final outcome.

Even in the midst of these challenges, impact analysis is evolving, taking advantage of several

auxiliary sources of methods and information: down-scaling methods are providing fine-resolution climate scenarios, either by statistically linking the large scales simulated by global climate models to local climate effects, or by dynamically coupling finer resolution, limited-area regional climate models to the coarser resolution, global models generating the long-term projections. Statistical analyses are increasingly performed to postprocess the results and determine probabilistic future scenarios, or at a minimum quantify ranges of uncertainties around the simple model projections. When a characterization of the uncertainty of the full range of values of a climate variable is not feasible, threshold analysis is substituted, where only relevant turning points, outside of a determined coping range for the systems concerned, are probabilistically treated. Climate impact studies apply a variety of threshold concepts, including physical, biological, social, and behavioral thresholds. Such thresholds either indicate a point beyond which the system in question fundamentally changes in response to climate change or crosses a subjectively defined “significant” level of impacts. The selection of meaningful and applicable thresholds for risk assessment is not a trivial task. Often, a bottom-up approach is taken to determine these relevant thresholds by engaging representatives of the stakeholder communities. Examples include analyses of the enhanced risks of heat waves under future global warming [26], estimates of the extent to which historical climate change has increased mortality and disease spread and of the enhanced risk of health-related detrimental effects in the future [27], and quantitative assessment of damages to agricultural yields under different scenarios in Australia [28] and Southeast Asia [29].

Finally, there is growing scientific literature regarding integrated assessment (IA) modeling that combines scientific knowledge from the natural and social sciences to provide information that is relevant for the management of climate risks. Such modeling explicitly considers policy strategies for mitigating GHG emissions. Methods include scenario analysis – discrete or probabilistic impacts analyses of alternative emissions scenarios (see section titled “Uncertainties in Climate Modeling”); guardrail analysis – inverse analyses deriving emission ranges that are compatible with predefined constraints on temperature increase, climate impacts, and/or mitigation costs; cost–benefit analysis – generally employing

optimization models, which balance the costs of mitigation with the benefits of avoided climate impacts represented in monetary terms and produce an “optimal” solution highly dependent on model assumptions; and cost-effectiveness analysis – determining policy strategies that minimize costs and are compatible with specified constraints on future climate change or its impacts.

IA modeling techniques have been applied to a wide variety of policy questions relevant to risk management, including trade-offs in terms of mitigation costs and projected damages on different sectors and regions, implications of “wait-and-see” *versus* “hedging” approaches to emission controls, costs and benefits of differential strategies for investment in mitigation, adaptation and sequestration, and the influence of potential impacts from large-scale abrupt climate changes (such as collapse of the thermohaline ocean circulation) on policy decisions. They have also been applied generally to the assessment of response strategies to avoid “dangerous anthropogenic interference with the climate system”, the stated goal of Article 2 of the United Nations Framework Convention on Climate Change. See DeCanio [30] and Fussler and Mastrandrea [31], e.g., for further discussion of IA models and methods.

- A1 story line and scenario family: a future world of very rapid economic growth, global population that peaks in mid-century and declines thereafter, and rapid introduction of new and more efficient technologies.
 - A2 story line and scenario family: a very heterogeneous world with continuously increasing global population and regionally oriented economic growth that is more fragmented and slower than in other story lines.
 - B1 story line and scenario family: a convergent world with the same global population as in the A1 story line but with rapid changes in economic structures toward a service and information economy, with reductions in material intensity, and the introduction of clean and resource-efficient technologies.
 - B2 story line and scenario family: a world in which the emphasis is on local solutions to economic, social, and environmental sustainability, with continuously increasing population (lower than A2) and intermediate economic development.

Within each story line, quantitative projections in terms of population and economic growth were prepared, followed by full quantification of the implied emissions using integrated assessment models. The result consisted of 40 scenarios developed by six modeling teams, all considered equally valid, i.e., with no assigned probabilities of occurrence. Six groups of scenarios were drawn from the four families: one group each in the A2, B1, and B2 families, and three groups in the A1 family, characterizing alternative developments of energy technologies: A1FI (fossil intensive), A1T (predominantly non-fossil), and A1B (balanced across energy sources). Illustrative scenarios 1 were selected by the IPCC to represent each of the six scenario groups, and have formed the basis of most of the subsequent analyses of model output. In the current assessment report, three scenarios have been chosen to span the range of possible futures: A2 for high emissions, B1 for low emissions and A1B for intermediate emissions.

MASTRANDREA AND RICHARD L. SMITH

Appendix

SRES Scenarios

The SRES first developed story lines by combining factors along two dimensions: one spanning the distance between strong economic values and strong environmental values, and the other between increasing globalization and increasing regionalization. Four major story lines were put forward as follows:

Group Decision

The practice of risk assessment has been substantially influenced by the development of decision theory and its sister discipline, *Bayesian statistics* (see **Bayesian Statistics in Quantitative Risk Assessment**). However, despite the romantic image of the lone decision maker which underpins, for example, Edwards [1] or Savage [2], most risk related decisions impact on and involve multiple parties who may have interests which are not congruent (see **Expert Judgment**). Consider an example from nuclear-waste management: different communities and stakeholder groups within a country may have quite different views about where to site a waste repository, and indeed, about whether such a facility is needed at all, but if the decision is to be implementable, the decision process will have to involve many of these concerned parties (see **Hazardous Waste Site(s)**).

By itself, the presence of multiple involved parties does not necessarily mean that the decision will be made by a group. It may be that one party has the power to unilaterally achieve their goals and force others to live with the consequences, at least in the short term, as may be the case within a hierarchically structured organization. However, in situations where all parties have some degree of influence in determining what happens, it is meaningful to talk of a “group decision”.

Just as the theory of the individual decision maker can be developed from either a normative or a descriptive point of view, so too can the theory of group decision. In this article, two normative theories are contrasted, game theory (see **Game Theoretic Methods**) and social choice theory (see **Societal Decision Making**), with a descriptive theory – the social psychological theory of groups. This is by no means a complete survey of disciplines relevant to the study of group decision, and even within the disciplines which have been chosen for survey, only those concepts and results that have been particularly influential are presented. Significant controversies around interpretations are often glossed over, and to keep terminology simple, mathematical results are presented in more casual forms than is standard in the technical literature, so readers are referred to the original sources for full details.

Normative Approaches: Game Theory

Game theory [3, 4] provides one normative framework for understanding group decision situations. A game theoretic model consists of a set N of n players, each of whom has actions ($a_i \in A_i$, $i \in N$) available to them. The set of actions chosen by each player can be thought of as a profile or vector $\mathbf{a}$, with one entry from each A_i (i.e., $\mathbf{a} \in \prod_{i \in N} A_i$).

Each player i has a (nonstrict) preference ranking over these action profiles denoted by $\succsim_i$ and the corresponding strict preference ranking is denoted by $\succ_i$ (see **Utility Function**). By definition, any player would want to choose the action which would maximize the value of the realized action profile.

Game theory is conventionally divided into two parts, referred to as *noncooperative* and *cooperative* game theory. In the former, parties have to decide how to act in the absence of any ability to form binding agreements, prior to taking their actions; but in the latter, it is possible to form such agreements. In our nuclear-waste management example, if parties had to submit individual sealed statements of their position to some governmental agency, the situation might resemble a noncooperative game. On the other hand, if they had the opportunity to interact amongst themselves, and with the agency, and arrive at a joint position, it could resemble a cooperative one.

Noncooperative games often have no “solution”, in the sense that there may be no clearly best action for any given player. However, concepts which offer insight and understanding are on offer. One such concept is the idea of a *Nash equilibrium*, named after the mathematician and game theorist, John Nash.

Definition. A Nash equilibrium is an action profile $\mathbf{a} = (a_1, \dots, a_i, \dots, a_n)$ such that for every player i , $\mathbf{a} \succsim_i (a_1, \dots, a'_i, \dots, a_n)$ for all $a'_i \in A_i$.

Colloquially speaking, a Nash equilibrium is a configuration of actions such that no player can achieve an improvement by unilaterally changing only their own choice of action. As binding agreements are impossible in noncooperative game theory, having reached a Nash equilibrium, a group of players might stick there for some time: a Nash equilibrium is likely to be *stable*. Stability is surely a desirable characteristic of a solution, but there are excellent reasons why the Nash equilibrium cannot be considered a “solution” to a game in any simple way.

To see why, consider the famous game known as *Prisoner's Dilemma*. This game features, as players, two suspects who are being held, in separate cells, on remand pending trial. There is evidence to convict both on a minor charge (leading to 2 years in prison) but no evidence for the major offense (leading to 10 years) with which both are charged. The prosecutor makes both prisoners the same invitation: confess and implicate your partner. If one prisoner alone confesses, the prosecution will drop all charges against that person, but the partner will receive the full penalty of 12 years for both offenses. If both confess, both will be prosecuted for the major offense alone, leading to 10 years in prison.

One can imagine a structurally similar situation in the nuclear-waste management example. Suppose the agency asks two communities to submit sealed bids to "support" or "oppose" the establishment of a nuclear repository. If one community supports, the repository will be established on their doorstep, the worst result for them, but the best result for their counterparty. If both oppose, the repository will not be established at all, the third best outcome for both. But if both support, the repository will be established at some unpopulated third location intermediate between the two, the second best outcome for both. Clearly the temptation for both communities is to oppose. But this would result in the loss of the win-win intermediate site solution.

The *payoff matrix* for Prisoner's Dilemma is shown in Table 1. The pair of numbers in the cells represent a valuation of the associated consequence to Players 1 and 2 respectively (we shall suppose that these valuations are von Neumann–Morgenstern utilities, see **Utility Function**). Checking the cells to find Nash equilibria results in the discovery that each player has a unilateral improvement from (don't confess, don't confess) and the only equilibrium is at (confess, confess). (This corresponds to (oppose, oppose) in the site selection example.) Thus, although there are potential gains from cooperation, the players

Table 1 Payoff matrix for Prisoner's Dilemma

		Player 2	
		Don't confess	Confess
Player 1	Don't confess	3, 3	0, 4
	Confess	4, 0	1, 1

Table 2 Payoff matrix for Battle of the Sexes

		Player 2	
		Theater	Opera
Player 1	Theater	2, 1	0, 0
	Opera	0, 0	1, 2

may be driven by mistrust to what is the third best/second worst outcome for both of them.

A second game, called *Battle of the Sexes*, features a couple who wish to spend an evening together, either at the theater, or at the opera. Player 1 prefers the theater to the opera, and Player 2 prefers the opera to the theater. If the communities involved in the nuclear-waste siting example feel that they will be individually better off if a waste repository is established somewhere, *even if it is near them*, than otherwise, then the siting problem may resemble Battle of the Sexes rather than Prisoner's Dilemma.

The payoff matrix for Battle of the Sexes is as shown in Table 2. It is easy to check that both players have a unilateral improvement from (theater, opera) and (opera, theater), but neither have a unilateral improvement from (theater, theater), or (opera, opera): there are two Nash equilibria in this game. (Note that this double equilibrium structure depends on both players preferring to spend the evening together rather than not: if Player 1 had a preference for going to the theater alone to going to the opera with the partner, the normatively rational – indeed, dominating – course of action would be to unilaterally go to the theater.) Even if we make the game cooperative by supposing that players can make binding agreements prior to decision, it is not obvious what players should be advised to do.

We will run with the idea of a cooperative version of Battle of the Sexes, but to take the analysis one step further, we will suppose that the players have access to some device which generates a random number between 0 and 1, and they are prepared to stake whether to go to the theater or opera on the output of this device. To make this rule operational, they will have to choose a critical value, p , such that if the random number drawn is less than p , they will attend the theater, and if greater, the opera. While this introduction of randomization does not solve the problem, it does replace a disagreement about a discrete variable with a disagreement about a continuous variable, and this opens up the possibility

of a compromise solution based on a value of p strictly between 0 and 1.

Nash also proposed a solution to this sort of problem (the “Nash bargaining solution”) based on maximizing the product of the player’s utilities [5]. In our Battle of the Sexes example, Player 1’s utility from the randomized strategy would be $(2p + (1 - p))$ and Player 2’s would be $(p + 2(1 - p))$. The product of these two quantities simplifies to $2 + p - p^2$, and setting the derivative to 0 to find the maximum yields $p = 0.5$, for an expected utility of 1.5 for each player. Thus, for players facing symmetric payoffs, the Nash formula yields a symmetric solution. This is not a coincidence, as the Nash formula can be deduced from a small number of reasonable axioms of which this symmetry condition is one. An important feature of this solution is that it makes no assumptions about interpersonal comparability of utilities: scaling the utilities of either player by a fixed constant would yield precisely the same outcome.

Analytically, the Nash solution is an interesting device, but it can be overinterpreted. Nash himself talks about “fair” solutions to the bargaining problem, but what he means by this is not clear, and it may be doubted whether an ethically fair solution can be arrived at with such a restricted information set. Also, the use of randomized decision rules for serious decisions seems hard to justify [6]. While the Battle of the Sexes couple might use a randomizing device to solve their theater-opera dilemma, it is hard to imagine a randomized strategy being adopted in siting a nuclear-waste repository.

Various conclusions can be drawn from the game theory, but one response, in light of the limitations of the Nash equilibrium and bargaining solution concepts, is to argue that such situations call for regulatory intervention by society at large, for example, to bind players’ hands in the case of Prisoner’s Dilemma, or to break the stalemate between players by making some determinate choice in the case of Battle of the Sexes. Strategically minded players may themselves accept this sort of role for the state, even though it involves constraints on individual freedom of action: Hardin [7] describes this as “mutual coercion mutually agreed upon”.

Normative Approaches: Social Choice

Attractive as this response may seem, it raises a further problem: how is “society at large” to make a

choice? In representative democracies, citizens vote infrequently for representatives with a known position on various issues, and these representatives then take decisions on behalf of society throughout their term of office, although occasionally, when a significant decision looms, citizens may vote directly in a referendum. These national elections are commonly mirrored by the use of the voting mechanism locally, within constituencies, and by elected representatives themselves in parliament and in cabinet. In modern societies, then, voting is a prominent mechanism, and the organizing normative theory for the study of voting systems is referred to as the theory of “social choice”.

Formally, the setup for this new problem of social choice is similar to the game theory setup – the people ($i \in N$) are still the same as previously (although we will now call them “citizens” rather than “players”), and each have a preference ordering $\succsim_i$. In contrast to the game theoretic world, however, these preferences are defined not over action profiles listing individual actions, but rather over collective actions ($a \in A$). Social choice theory sees voting as a process by which by which citizens’ preferences are elicited and combined to yield a collective group ranking $\succsim_g$ (or $\succ_g$ in the case of the strict part).

A solution honored by custom and practice is *majority voting*, but it has been known for more than a century (Nanson [8], as cited by Sen [9]) that this can lead to odd consequences. Consider three citizens whose preference orderings are as shown in Figure 1: citizen 1 prefers a to b to c ; citizen 2, b to c and c to a ; and citizen 3 prefers c to a and a to b . In a vote for a against b , a will receive two votes; in a vote for b against c , b will also receive two votes; and in a vote for c against a , c will receive two votes. Thus majority voting on a pairwise basis yields a cyclical or intransitive system of preferences: a beats b beats c beats a . As transitivity is a fundamental principle of rational choice (see **Utility Function**), this is a little disconcerting.

Disconcerting it may be, but not disastrous. There are many ways other than majority voting of combining preference orderings. Nanson’s paradox shows the limitations of one approach, but it also poses an intriguing question: can we find some method of combining individual preferences that is, in general, satisfactory in some sense?

To consider this, we need a little more formality. A way of combining individual preference orderings

Figure 1 Preference orderings leading to intransitive social choice

$\succsim_i$ which yields a group ordering $\succsim_g$ can be called a *constitution* [6]. Note that on this definition, majority voting is not a constitution, as it does not yield a well-defined ordering. Clearly, the number of possible constitutions, logically speaking, is very great, and one might expect that it would be very hard to say anything conclusive at all. As it happens however, this, the field of social choice is dominated by a single, definitive result: Arrow's theorem [10]. This theorem shows that, for situations with at least two citizens and at least three alternatives, no constitution can be found which satisfies four seemingly very innocuous conditions.

The four key conditions are often stated as axioms.

The first axiom, *nondictatorship*, says that no citizen can dictate the group preference ordering. This is essentially a nontriviality condition: obviously dictatorships do exist, and, perhaps, there may even be situations where dictatorships may be desirable (e.g., in crisis situations where time is very scarce), but this form of preference aggregation can clearly not be considered a meaningful solution to the problem of group decision.

Axiom D Nondictatorship. *There is no i such that for all $a, b \in A$, $a \succsim_i b$ implies $a \succsim_g b$.*

The second axiom, *unrestricted domain*, says that the constitution must be defined for all profiles of preference ordering on the part of citizens. Again, this is a nontriviality condition: we must work with the preference orderings with which citizens present us, whatever they may be. If we wish to restrict the domain of preference orderings, we would have to exclude citizens who had the sort of preference orderings we regard as pathological.

Axiom U Unrestricted domain. $\succsim_g$ is defined for all possible $\succsim_1, \succsim_2, \dots, \succsim_n$.

The third axiom is the *Pareto principle*: it says that if *all* citizens prefer one action to another, then the group collectively should prefer one action to another. The Pareto principle is a foundation stone of welfare economics, and is almost completely uncontroversial (but see discussion of Sen's theorem below). Indeed, one could argue that if all citizens prefer one action to another, then there is no social dilemma: in this sense, the Pareto principle can be considered to be almost a nontriviality condition.

Axiom P Pareto principle. *If, for some $a, b \in A$, $a \succ_i b$ for all i , then $a \succ_g b$.*

To understand the fourth and final axiom, it helps to think procedurally. Suppose that we aggregate preferences, using some constitution. At some point, we find that some action we thought was available, is not, in fact, available: it has to be deleted from the action set. (In Arrow's original monograph, he gives the example of an election, during the course of which one of the candidates dies.) Should it matter to the final result whether we make this discovery *prior to* aggregation (and so all our citizens delete the action from their preference ordering) or *subsequent to* aggregation (in which case we delete the action from the derived social ordering)? If it does make a difference, given a suitable profile of preferences amongst the citizenry, an unscrupulous politician could conceivably manipulate the results of the election by adding or deleting items from the election list. This seems obviously undesirable, and so it is plausible to claim that it *should not matter* when we delete the action. This axiom is called *independence of irrelevant alternatives*.

It should be noted that some prominent, and popular systems of voting do not respect this principle. For example, consider a system, known as the *Borda method*, which assigns points to actions based on citizen ranks. Specifically, if there are six possible actions, the point score for citizen i for an action is $7 - r_i$, where r_i is the rank given by citizen i , and the collective ordering is based on the aggregate points for each action. Suppose moreover, that citizens rank actions as shown in the first panel of Figure 2: then a (13 points) is collectively strictly preferred to d (12 points) under this constitution. However, if c is deleted from the preference orderings of the citizenry,

Figure 2 The social ordering from a rank points scheme can be reversed by deletion of irrelevant actions

as shown in the second panel, then a gains one point from its resulting move up the rankings, but d gains two points, with the result that a and d draw neck and neck. Deleting b leads to a system of preference orderings in which d is now the outright victor in the social ordering.

Axiom I Independence of irrelevant alternatives.

Consider two possible profiles of public preferences $(\succsim_1, \succsim_2, \dots, \succsim_n)$ and $(\succsim'_1, \succsim'_2, \dots, \succsim'_n)$, and call their aggregations under the constitution $\succsim_g$ and $\succsim'_g$ respectively. Consider also a subset A^* of A (i.e., delete one or more actions from A). If, for all citizens i , and for all pairs of alternatives $a, b \in A^*$, $a \succsim_i b \Leftrightarrow a \succsim'_i b$ (i.e., the citizen's rankings on the restriction of A to A^* are the same), then $a \succsim_g b \Leftrightarrow a \succsim'_g b$ (i.e., the collective ranking is the same).

It is now possible to present Arrow's theorem.

Theorem 1 (Arrow's theorem). *There is no constitution which combines $\succsim_1, \succsim_2, \dots, \succsim_n$ to yield $\succsim_g$ in a manner consistent with all of D, U, P, and I.*

Versions of the proof of Arrow's theorem are presented in Arrow [10], Sen [9], and French [6].

Arrow's theorem packs a powerful punch. Although the theorem is weakened if the citizen's preference orderings can be constrained to those of a certain structure ("single peakedness"), there is no easy way to defeat the result. The most promising

avenue is to expand the frame, including more information which allow statements relating to the relative interpersonal intensity of preferences to be made ("X prefers a to b more strongly than Y prefers c to d "). This raises the question of who is to make such profoundly difficult judgments in the absence of some supra decision maker (see **Supra Decision Maker**).

A further depressing result in the same vein, the impossibility of a Paretian Liberal (IPL), is due to Sen [9]. Sen observes that an attractive principle of many choice rules is liberalism: for choices between actions which pertain to me and me alone (e.g., my private religious observances or sexual practices), the social ordering should respect my preferences. In the case of the nuclear-waste siting example, a liberal position might be that local communities should have to give their consent to having a repository (perhaps supplemented with certain inducements) sited in their locality. This idea is formalized through a further axiom.

Axiom L Liberalism. *For each person i , there is a nonempty subset A_i containing at least two actions, and for $a, b \in A_i$, if $a \succ_i b$, then $a \succ_g b$.*

Obviously, the practical implication of this axiom rather depends on the precise content of A_i (smoking in restaurants, making provocative statements about others' religious beliefs). But formally, the interesting

thing about L is that it opens the way to another impossibility theorem.

Theorem 2 (IPL). *There is no constitution which combines $\succsim_1, \succsim_2, \dots, \succsim_n$ to yield $\succsim_g$ in a manner consistent with all of U , P , and L .*

The full proof of IPL is presented in Sen [9], but to give a flavor, consider the following variation on the nuclear-waste siting example. Geological investigation has determined that two localities are suitable for siting a repository, around Alphatown and around Betaville. The social action set contains three actions, siting the repository at Alphatown (a), siting the repository at Betaville (b), and not building a repository at all (c). The inhabitants of Alphatown do not favor building a repository as a solution to the nuclear-waste management problem. However, they are not economically well-off, and the community would benefit from the investment if a repository were to be built locally, so if it is to be built, they would rather it be built nearby. In Betaville, on the other hand, there is enthusiasm for the repository solution in principle, but Betaville residents do not lack for the material things of life and would prefer the repository to be sited elsewhere. These preferences are shown in Figure 3, with the actions in each respective A_i shown in bold.

The stage is now set for the main trick. Liberalism requires that since Betaville prefers b to c , $b \succ_g c$, and since Alphaville prefers c to a , $c \succ_g a$, and the Pareto principle requires that since both prefer a to b , $a \succ_g b$. But this leads to $b \succ_g c \succ_g a \succ_g b$, a cycle, and so the relation $\succ_g$ is not a true ordering. This unsettling result illustrates that the

Figure 3 Preference orderings in the Paretian Liberal example

liberalism principle and the Pareto principle can be incompatible: no well-defined constitution exists which can be guaranteed to always do both.

Looking back across game theory and social choice, the reader may feel a sense of disappointment. The normative theory of the individual decision maker gives us subjective expected utility theory (see **Subjective Expected Utility**) and multiattribute value theory (see **Multiattribute Value Functions**), but the normative theory of group decision gives us no uniquely satisfying theoretic framework for making group decisions, like our nuclear-waste repository siting decision. One might expect that this would mean that the scope for descriptive research on group decision is limited, since what has driven the corresponding research program on individual decision making since its inception [1] is the contrast between the behavior of the idealized “perfectly rational” decision maker and what real people actually do.

Descriptive Approaches: Social Psychology

Yet, descriptive research on group decision and performance, more generally, has flourished within the discipline of social psychology [11, 12]. Although the explicit connection between the normative and descriptive aspects of group decision are weaker than in the case of individual decision, there is considerable resonance between the key concepts of the two areas of research. Indeed, the social choice concept of a constitution has an analogue in the descriptive theory in the concept of a *decision rule*, which “specifies, for any given individual set of preferences regarding some set of alternatives, what the group preference or decision is regarding the alternatives” [13, p. 327].

A concept related to (but distinct from) that of the decision rule is a *decision scheme matrix (DSM)* [14–16], a notion which has been particularly popular in the study of jury decision making. These matrices (called *DSMs* here) capture *descriptively* how individual preferences, stated prior to interaction, relate to a group decision. A DSM thus is an input–output model and can be fitted to particular data sets obtained from experiments with decision making groups (for example, mock juries) in laboratory settings.

The structure of a DSM is as follows. The columns are indexed after the set of actions A , and the rows of the matrix are indexed by possible *ex ante*

Table 3 Examples of decision scheme matrices

Distribution of support		D_1		D_2		D_3		D_4		
a	b	a	b	a	b	a	b	a	b	Hang
5	0	1	0	1	0	1	0	1	0	0
4	1	1	0	0.8	0.2	1	0	0	0	1
3	2	1	0	0.6	0.4	1	0	0	0	1
2	3	0	1	0.4	0.6	1	0	0	0	1
1	4	0	1	0.2	0.8	1	0	0	0	1
0	5	0	1	0	1	0	1	0	1	0

distributions of support given by group members for each action $a \in A$. The quantities in the cells represent probabilities of the group *ex post* choosing a , given such and such a distribution of support. A number of DSMs for five persons and two actions are shown in Table 3. D_1 describes a situation where the majority preference wins out. D_2 describes a “proportionality” model, where the probability of the final decision being some given action is proportional to the support for that action. In D_3 , as long as at least one person chooses a , the social decision is a : this rule is sometimes called *truth wins* and is appropriate for decisions where the correct answer is obvious as soon as one person has found it (e.g., in a task like the taking of square roots). D_4 models a situation where unless there is complete prior consensus on one action or another, the group will “hang” and fail to come to a decision.

The relationship between DSMs and decision rules is not one-to-one. D_1 , for example, could summarize behavior in a group using majority voting. It could also summarize behavior in a group which does not use an explicit decision rule at all, but comes to a decision based on the chair’s assessment of the “balance of opinion”. It could even summarize the behavior of a jury which has been instructed to use a consensus decision rule, but where, through the process of deliberation, preferences change, and eventually all group members converge on the same verdict.

Understanding how preferences may change in interacting groups has been a central aim of social psychological research on groups. Two possible ways of accounting for preference shift are in terms of *information processing* (as the group has shared all relevant information about the problem at hand, there is less room for disagreement); and in terms of *conformity to majority opinion*. A seminal example

**Figure 4** Cards in Asch’s experiment

of experimental work on the latter is that of Asch [17]. Subjects in Asch’s experiments were told that they were participating in a test of visual abilities. They were then placed in a group of apparent fellow subjects (actually confederates of the experimenter), and in a series of eighteen trials, they were presented with two cards, a standard card and a test card, as illustrated in Figure 4. Group members were asked to declare in sequence which of the lines on the test card was equal in length to the line on the standard card, with the actual subject declaring last. On twelve of the trials, the confederates would systematically declare a wrong line (e.g., the rightmost line on the test card in Figure 4) to be equal to the standard line. Although the right answer to the task is obvious, and subjects had no difficulty in arriving at the correct answer when tested alone, 76% of subjects gave at least one incorrect answer in the group setting, demonstrating the hold which majority opinion can have on an isolated (but correct) subject.

Conformity to majority opinion is a recognizable phenomenon. However, if everyone conformed, society would rapidly degenerate into an intellectual monoculture, and insofar as this has not happened, the conformity account of opinion change is incomplete. Alongside the conformity research, a separate research tradition has studied the ways in which a

minority can influence majority opinion. A key lesson from this research is the importance of behavioral style. In particular, experimental studies show that a minority which reliably calls blue lights green can eventually change majority definitions of green and blue, but this effect does not exist when the minority is not consistent [18]. Although conformity to majority opinion and minority influence may appear to be opposite, they are in fact closely linked: the reason that minorities can be influential is precisely because majorities recognize that minority status is uncomfortable, and so conclude that obstinate minorities must have some good reason for their persistence.

Both majority and minority influence are examples of the general phenomenon of *social influence*, “a change in the judgments, opinions, and attitudes of an individual as a result of being exposed to the judgments, opinions, and attitudes of other individuals” [19]. Researchers distinguish two different types of influence, *normative* and *informational* influence. Normative influence arises from the suppression of a view through a reluctance to express overt dissent, and may lead to *public compliance* with the influencers, with no change in underlying opinion. Informational influence occurs when the influencer concludes that it is more likely that his own judgment is faulty than that everyone else is wrong, and may lead to *private acceptance* of a new belief.

Studies of majority and minority influence shed some light on the mechanisms of opinion formation in groups, but do not give a sense of how these effects might play out in a freely interacting group. Yet, systematic patterns do exist. One counterintuitive, yet robust, example is *polarization*, which relates to a tendency for group decisions arising out of unstructured interaction to be more extreme than would be suggested by individual attitudes elicited prior to interaction. For example, if a group is asked to select the maximum level of riskiness at which they would consider it reasonable to submit to some curative surgical procedure, and group members tend to be at the more cautious (more risky) end of the scale, the level of risk of the option preferred by the group will tend to be lesser (greater) than the average level of risk of the preferred options of individual group members.

Explanations for polarization based on both a *persuasive arguments* and a *mere exposure* rationale have been suggested [20], although other modes of

explanation do exist [21]. The idea behind the persuasive arguments account is that if group members tend to lean to one direction, the pooling of the arguments behind these individual preferences will tend to lead to a more pronounced group position. Mere exposure accounts, on the other hand, are predicated on one of two mechanisms, either the *removal of pluralistic ignorance*, or *one-upmanship*. Removal of pluralistic ignorance accounts emphasize that group members’ originally stated preferences may underrepresent the true extremity of their true preferences for purposes of conformance: as it becomes clear that the center of opinion is off-center in one direction, this caution is muted. One-upmanship effects, in contrast, are predicated on the notion that people tend to favor positions which are more extreme in a socially valued direction. Experimental evidence for all these effects exists, and polarization seems to be a composite phenomenon, arising out of a number of different processes, the relative contribution of which depend on local context.

A well-known application of social psychological ideas such as social influence and polarization to the understanding of policy making is that of Janis [22], who coined the popular notion of “groupthink” and used it to analyze a number of policy “fiascoes” such as Kennedy’s Bay of Pigs invasion of Cuba, and the failure of the US Navy to prepare for attack at Pearl Harbor. Janis’ argument is that in these cases, a combination of high group cohesion, time pressure, strongly directive leadership, and isolation (frequently self-imposed) from other sources of information, led to gross overconfidence on the basis of manifestly inadequate analysis.

In the context of nuclear-waste management, it is interesting to note that current practice has moved away from the decide-announce-defend (DAD) model, where a small group of nuclear insiders would propose a management solution based on a technical analysis. Instead the fashion is for more consultative processes designed to be open to external scrutiny and to involve a broad spectrum of society with a diverse range of viewpoints (see Pescatore and Vári [23] for a review of practice in a number of OECD countries). Although the reasons given for this shift are typically in terms of bolstering public trust, from a social psychological point of view, DAD seems set up to produce groupthink. Consequently, a more participative model of decision making in such situations may not only lead to greater public confidence, but

may also lead to an improvement in the quality of the decisions made.

In this section, we have surveyed some key ideas in the social psychology of group decision. Although the *explicit* connection between this body of research and the normative research described in previous sections is not particularly strong, descriptive research can be seen as calling into question the notion of a fixed system of preferences which the normative theory postulates. Some recent research, for example, the growing body of work on behavioral game theory [24, 25], enriches the formal frameworks of the normative research with behavioral insights about endogenous preference change. There is a parallel here with the way in which the theory of the individual decision maker has developed: prospect theory and its competitors attempt to build a formalized descriptive theory which generalizes *subjective expected utility theory* (see **Subjective Expected Utility**). However, a review of this work is beyond the scope of the current article.

Conclusion

This review article has canvassed some highlights of normative and descriptive research on group decision, sketching some key ideas from game theory and social choice on the one hand, and from the social psychological study of groups, on the other. A central contrast has been between a normative theory which takes as exogenously given an action set and a system of individual (“player”, “citizen”) preferences over these actions, and a descriptive theory, which focuses on how preferences change as a result of group interaction.

A second contrast has been between the theories of individual and group decision making. The decision theory of the individual decision maker, at least as interpreted by its proponents, provides in subjective expected utility and multiattribute value theory a satisfying account of how decisions *should* be made. The theory of group decision, on the other hand, does not offer any such comfort. Rather, it throws into focus the drawbacks of particular attractive solution concepts such as the Nash equilibrium and bargaining solution in the case of game theory, or majority voting and the Pareto and liberalism principles, in the case of social choice.

In practice, group decisions about how risks are to be managed do get made, but often they are made

badly in ways that the theory warns us about: they may be unfair, unsustainable, arbitrary, or based on poorly shared information, or deliberately or accidentally suppressed dissent. Fortunately, a growing body of research and practice in the management of societal risks studies show that it is possible to design decision processes which make appropriate use of risk and decision analytic technologies, but which are also responsive to the social context in which the decision takes place. The reader is referred to other articles in this encyclopedia for a more thorough discussion (see **Decision Conferencing/Facilitated Workshops**).

Hazard and Hazard Ratio

General Discussion of Mathematical Concept of Hazard

Hazard or the hazard function arises in the context of *survival analysis*, also known as *failure analysis*, or more generally analysis of the time to event. Examples include months of survival after treatment for cancer, the time to first repair of consumer products, time from installation to first leak of a roof, or time to wear out of a new automobile tire. The time variable may be age, calendar time, time in use, duty cycles, miles driven, or any other variable that tracks the aging process of the system under study. The hazard function describes the current chance of failure for the population that has not yet failed.

In general, let T represent a random variable that is the time to event. Further, let F be the cumulative probability distribution function of time, or age, to failure, i.e., $F_T(t) = \text{probability}\{T \leq t\}$. The survivor function $S_T(t) = 1 - F_T(t)$ is the proportion of the population that survives up till time t ; $S_T(t) = \text{probability}\{T > t\}$. In engineering applications this is sometimes referred to as the *reliability function*.

The hazard function at time t is the conditional probability of failure, conditional upon survival up to time t . Many of the failure time models are more easily described through the hazard function, h_T .

$$\text{Specifically, } h_T(t) = \lim_{\Delta \rightarrow 0} \frac{1}{\Delta} \frac{[F_T(t + \Delta) - F_T(t)]}{F_T(t)} \quad (1)$$

If the hazard function is constant, it means that the probability of failure is constant; it does not depend upon age, time in service, or number of duty cycles. If the hazard function is increasing with time, it describes an aging, or wear-out, process, i.e., the older the units under study, the higher the failure rate of the remaining units. If the hazard function is decreasing, it describes an infant mortality or burn-in process, i.e., the longer the units have survived, the lower the failure rate for the remaining units.

Many processes have a U-shaped hazard function. This is called the *bathtub* curve and describes the fact that many processes, including human life, are subject

both to infant mortality and to aging and wear-out. There is a high failure rate early on in the process (in humans a high death rate in the first month of life), followed by a period of low mortality or low failure, until a certain age is attained and the mortality rate or hazard function accelerates. Figure 1 illustrates these hazard patterns.

Hazard Functions for Some Typical Survival or Failure Time Models

The exponential, Weibull, and lognormal distributions are three of the commonly used statistical models of time to failure. The hazard function describes the failure process and provides a convenient way to visualize how the risk of failure changes with age or time.

Exponential

The exponential model is the simplest of the time to failure models. It is the memory-less process. The hazard does not change with time. The probability of failure for the surviving units does not depend upon previous history of the units. The survivor function is $S_T(t) = \exp(-\lambda t)$, and the probability distribution function is $1 - \exp(-\lambda t)$. The hazard function is given by

$$\begin{aligned} h_T(t) &= \lim_{\Delta \rightarrow 0} \frac{1}{\Delta} \frac{[F_T(t + \Delta) - F_T(t)]}{F_T(t)} \\ &= \frac{[d\{1 - \exp(-\lambda t)\}/dt]}{\{1 - \exp(-\lambda t)\}} = \lambda \end{aligned} \quad (2)$$

Weibull

The Weibull family of distributions is a flexible family of time to event distributions that allows both increasing and decreasing hazard functions. It is the most popular parametric model of time to failure in engineering applications. Despite its flexibility, it does not permit a hazard function that is both decreasing over part of the range and increasing over part of the range, as would be needed to model the bathtub curve type of hazard function. The bathtub curve can be modeled as a mixture of two Weibull functions, one with a decreasing hazard function and one with an increasing hazard function (see Figure 2).

Figure 1 Three typical hazard functions

Figure 2 Hazard functions for the Weibull family

The survivor function for the two parameter Weibull family of distributions is $S_T(t) = \exp[-(t/\beta)^\alpha]$, and the hazard function is $\alpha/\beta[t/\beta]^{(\alpha-1)}$. The parameter β is a scale parameter and α is the shape parameter. If α is less than 1, the hazard function is decreasing; if α is greater than 1, the hazard function is increasing. When $\alpha = 1$ the Weibull function reduces to the exponential function.

In some applications a third parameter, τ_0 , the threshold, is added. In this case, it is assumed that there is no risk of failure prior to τ_0 , i.e., the hazard is zero prior to τ_0 . This is equivalent to shifting the timescale by τ_0 .

Lognormal

Here the logarithm of the time to failure follows the normal or Gaussian distribution. The survivor function is $S_T(t) = \Phi[-\log(t) - \alpha]/\sigma]$, and the hazard

Figure 3 Hazard functions for the lognormal family

function is $\phi[\log(t) - \alpha]/\sigma]/\{\Phi[-\log(t) - \alpha]/\sigma] \times [(\log(t) - \alpha) \times \sigma]$, where Φ is the standard normal probability distribution function and ϕ is the standard normal density function. Hazard functions in the lognormal family are unimodal. If σ is greater than 1, the peak will be at zero and the hazard will be strictly decreasing. If σ is 1 or less, the hazard will be zero at $t = 0$, rise to a peak and then decrease (see Figure 3).

Nonparametric and Semiparametric Models

The life table method can be used to estimate hazard functions with no predetermined shape. This method is frequently used in medicine and epidemiology with some application in the fields of finance and economics. It provides an extension of the ideas of linear regression to the realm of survival analysis. The parameters of the model have a natural interpretation as relative risks.

The hazard function is estimated as a piecewise linear function, with constant hazard at each age group in the life table. The precision of this type of analysis is limited only by the precision of the age groupings.

The Cox proportional hazards method models the hazard function as follows:

$$h_T(t) = \lambda_0(t) \exp(\gamma + X\beta) \quad (3)$$

where $\lambda_0(t)$ is a base hazard function of unspecified shape, X is a vector of risk factors measured on each subject, and β is a vector of parameters describing the relative risk associated with the risk factors. This method may be considered semiparametric as no assumptions are made about the base hazard

function, but the effect of the risk factors is assumed to be linear in the log of the hazard function. If the risk factors are indicator functions, then there is no restriction and the model is fully nonparametric.

Hazard Ratio

The hazard ratio is a way of comparing the relative risk of failure associated with two groups. It is perhaps easiest to understand in the context of a simple Cox proportional hazards model. Assume that there is only one risk factor X , which takes the value 1 if the high risk condition is present and 0 if not. In this case, it is natural to compare the hazard function for the high risk condition, i.e., $h_T(t|X = 1) = \lambda_0(t) \exp(\gamma + \beta)$, to the hazard function for the low risk condition, $h_T(t|X = 0) = \lambda_0(t) \exp(\gamma)$.

The hazard ratio is simply given by

$$\frac{h_T(t|X = 1)}{h_T(t|X = 0)} = \exp(\beta) \quad (4)$$

This represents the instantaneous relative risk conditional upon survival until time t .

This may be the most direct way to measure relative risk in the time to failure context. Relative risk, as measured by the probability of failure in the high risk group compared to the probability of failure in the low risk group, will of course depend upon the time period during which the two groups are exposed to risk of failure. All groups will eventually reach end of life, and in the absence of competing risks, the relative risk will tend to 1.0 as the time increases. If we choose a particular time τ , the relative risk of failure up until time τ can be calculated from the hazard function as

$$RR = \frac{F_T(t|X = 1)}{F_T(t|X = 0)} \quad (5)$$

$$RR = \frac{\left\{ 1 - \exp \left[- \int_0^t \lambda_0(u) \exp(\gamma + X\beta) du \right] \right\}}{\left\{ 1 - \exp \left[- \int_0^t \lambda_0(u) \exp(\gamma) du \right] \right\}} \quad (6)$$

for the proportional hazards model.

In the typical proportional hazards analysis, the baseline hazard, λ_0 , is neither known nor estimated from the data. Thus, it is not possible to estimate or

calculate a direct measure of relative risk, or odds ratio, for any particular time t .

In general, the relative risk at time t is given by

$$RR = \frac{\left\{ 1 - \exp \left[- \int_0^t h_T(u|X = 1) du \right] \right\}}{\left\{ 1 - \exp \left[- \int_0^t h_T(u|X = 0) du \right] \right\}} \quad (7)$$

If the hazard ratio is known or estimable from the data, it will be possible to calculate the relative risk using this formula.

Hazard Ratio Patterns

Constant Hazard Ratio. The Cox proportional hazard model is one form of constant hazard ratio – that is, the hazard ratio is constant, conditional upon the value of the vector of covariates. If the hazard is assumed to depend only upon the current value of the covariates, the covariates can be allowed to change with time without loss of generality in the model.

In any model in which the hazard ratio is assumed to be constant, the interpretation of the hazard ratio as instantaneous relative risk is understandable. Another interpretation is the relative “force or mortality”, i.e., the relative probability of transitioning from the prefailure to the failure state.

Average Hazard Ratio. In many situations, the assumption of proportional hazard ratios may be unrealistic. Kabfleish and Prentice [1] developed a simple noniterative estimate of the average hazard ratio for the two-sample problem. The idea is to take a weighted average of the hazard ratio:

$$\text{Average hazard ratio} = \int_0^\infty \frac{h_T(u|X = 1)}{h_T(u|X = 0)} dG(u) \quad (8)$$

where G is a suitable weight function. G can be chosen to put the most weight during periods that are *a priori* determined to be the most important.

If the hazard ratio is always greater than 1.0 (or always less than 1.0), then group $X = 0$ has better (or worse) survivability than group $X = 1$ for all time periods. In this case, the average hazard ratio has a fairly straightforward interpretation. However, if the hazard ratio is greater than 1.0 for some ages and less than 1.0 for other ages, the average hazard ratio is

difficult to interpret. A group with the average hazard ratio less than 1.0 can have poorer survivability than the comparison group. For example, a group with high infant mortality and low hazard for older ages may have average hazard ratio less than 1.0 when compared to a group with low infant mortality and higher hazard for older ages, and yet at each age a higher proportion of the comparison group has survived. In this case, the high infant mortality outweighs the low hazard at older ages. The result is a misleading average hazard ratio.

Statistical Methods

Here we describe a general nonparametric method for describing the relative risk of failure for two or more populations. The method is very flexible in that no assumptions about the underlying form of hazard function are needed.

Rank Tests for Comparison of Survival Curves

For ease of interpretation, we start with a comparison of two groups, e.g., a treated group and a control group. The rank tests that we describe can be then generalized for the comparison of several groups. Here n_1 is the sample size from the first population, n_2 is the sample size from the second population, and $n_1 + n_2 = m$. Let h_{Ti} be the hazard function for population i .

If $h_{T1}(t) = h_{T2}(t)$ for all t , the survival distributions are the same for the two populations, and *vice versa*. Consequently, a test for equality of haz-

no censoring, a two-sample rank test such as the Wilcoxon could be used. Typically, the data does include censoring, i.e., not all subjects are observed till failure; for some subjects we only know that the time to failure is greater than the observed time under study. Generalization of the Wilcoxon test for this situation was proposed by Gehan [2] in 1965 and Breslow [3] in 1970. Mantel [4] and Cox [5] proposed the log-rank test for this problem in 1966 and 1972, respectively.

Let $t_1 < t_2 < t_3 < \dots < t_k$ be distinct times at which failures were observed. Further, let O_{ij} be the number of failures observed in the i th group at time t_j and R_{ij} be the number of observations in the i th group at risk immediately prior to time t_j . Let R_j be the total observations in both groups at risk immediately prior to time t_j and O_j be the total number that fail at time j .

Tarone and Ware [6] showed that both the log-rank test and the Gehan modification of the Wilcoxon test are part of a general class of statistics based upon comparing the observed number of failures at each time to the number of failures expected under the null hypothesis of equal distribution of time to failure, and summarizing across the k distinct failure times *via* a χ^2 statistic.

Specifically, let $v' = (v_1, v_2)$ where

$$v_i = \sum_{j=1}^k W(t_j) \times \{O_{ij} - E_{ij}\} \quad (9)$$

where E_{ij} is the expected number of failures in group i at time $t_j = O_j \times R_{ij}/R_j$.

Let $\mathbf{V}$ be the estimated covariance matrix of v :

$$\mathbf{V}_{i1} = \sum_{j=1}^k W^2(t_j) \times \left\{ \frac{[O_j \times (R_j - O_j) \times (R_j \times R_{ij}d_{i1} - R_{ij} \times R_{1j})]}{[R_j^2 \times (R_j - 1)]} \right\} \quad (10)$$

and functions is equivalent to a test of equality of survivor distributions.

Rank tests for comparing two survival curves are similar to other two-sample rank tests. We rank the times to failure for the pooled sample. If the two populations have the same distribution of time to failure and there is no censoring, the values of the ranks for group 1 will be like a random sample, without replacement of a sample of size n_1 from the integers $1, 2, \dots, m$. In the case of

Then the test statistic $S_w = v'\mathbf{V}^{-1}v$ will have a χ^2 distribution with one degree of freedom, where $\mathbf{V}^{-1}$ is the generalized inverse of $\mathbf{V}$.

W is a weight function that specified the test. The commonly used examples of this type of test are as follows:

$$\text{Wilcoxon: } W(t_j) = R_j \quad (11)$$

$$\text{Log rank: } W(t_j) = 1.0 \quad (12)$$

$$\text{Tarone-Ware: } W(t_j) = R_j^{1/2} \quad (13)$$

$$\text{Peto-Peto: } W(t_j) = \prod_{l=1}^{j-1} \left\{ \frac{1 - O_l}{(R_l - 1)} \right\} \quad (14)$$

This shows that the commonly used rank methods are all in the same class of tests. This general mathematical formulation facilitates the derivation of the properties of the tests.

This method can be generalized to comparisons of k populations, in which case the test statistic, S_w , will have a χ^2 distribution with degrees of freedom equal to the rank of $\mathbf{V}$ under the null hypothesis that all of the populations have the same distribution of time to failure.

These χ^2 tests are similar to the test for partial association in contingency tables (see Gart [7]).

The log-rank test is more powerful when the hazard ratio is, in fact, constant as in the Cox proportional hazards model. These tests are easily generalized for covariates that are more general indicators of the population from which the observations were drawn (see Kabfleish and Prentice [8, chapter 6]).

Examples

Medicine and Public Health

The Cox proportional hazard model or other hazard ratio models are commonly used in clinical trials and epidemiology. The proportional hazards model can be used in retrospective or case-control studies as well as in traditional prospective time to failure analyses.

One recent example of use of hazard ratio models is the study of survival time after the death or hospitalization of a spouse, by Christakis and Allison [9]. They studied more than half a million couples over age 65 who were enrolled in Medicare in the United States in 1993. This was a prospective study with nine years of follow-up.

Higher risk of death was found after the death of a spouse for both men and women. The risk of death was also increased following hospitalization of the spouse for dementia, psychiatric disease, hip fracture, or stroke; risk of death was not statistically significantly elevated after hospitalization of the spouse for colon cancer.

Environment

Survival analysis and the hazard ratio are used in environmental and ecological applications (see **Environmental Health Risk; Environmental Hazard**). In a recent edition of Fisheries and Aquatics Bulletin, scientists for the US Geological Survey [10] used the estimated hazard ratio to develop a disease infection model. The hazard ratio was used to compare mortality rates for rainbow trout, walleye, and catfish that were infected with *Flavobacterium columnare* to mortality rates of noninfected controls of the same species.

Finance

Mehran and Peristani [11] used the Cox proportional hazards model to evaluate the decision to return to private status among small businesses that had recently gone public with an initial public stock offering. Firms with low stock turnover, small institutional ownership of the stock, and small growth in coverage by financial analysts were seen to be more likely to return to private ownership, and to do so in a shorter period of time, than firms with high analysis coverage, institutional ownership, or high volume of trading.

Summary

The hazard function is a tool for describing the process of time to failure. It is used in epidemiology, medicine, ecology, engineering, and manufacturing settings, as well as in economics and finance. The formula for the hazard function is simpler and easier to interpret than the survivor function or the probability distribution of time to failure.

The hazard ratio is a general way of examining relative risk. In particular, Cox proportional hazards models are flexible and allow introduction of covariates to model the failure process. The parameters of the Cox model are usually interpretable as relative risk.

Hazardous Waste Site(s)

In general terms, hazardous waste sites are portions of land contaminated by voluntary or involuntary introduction of hazardous substances, such as improper management or disposal of waste and accidental spills or voluntary discharge of substances. In regulatory terms, the same terminology may have different meaning from country to country. In the United States “hazardous waste sites” are regulated under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), commonly known as *Superfund*, enacted by the US Congress in 1980. A waste is considered hazardous if it exhibits one or more of the following characteristics: ignitability, corrosivity, reactivity, or toxicity (*see What are Hazardous Materials?*). In the European Union regulatory framework, although classifications of hazardous waste and dangerous substances are provided (Directive 91/689/EEC, Directive 67/548/EEC), the term *hazardous waste sites* is not used. The more general term *contaminated sites* is used to indicate local soil contamination.

The most common contaminants found at hazardous waste sites are as follows:

- some heavy metals and metalloids, like *lead* (*see Lead*), manganese, *arsenic* (*see Arsenic*), copper, nickel, cadmium, chromium, zinc, barium, *mercury* (*see Mercury/Methylmercury Risk*), antimony, beryllium;
- aromatic hydrocarbons, like *benzene* (*see Benzene*), toluene;
- polycyclic aromatic hydrocarbons (PAHs), like naphthalene and benzo(a)pyrene;
- chlorinated hydrocarbons, like vinyl chloride, dichloroethane, trichloroethane, trichloroethylene, tetrachloroethylene, carbon tetrachloride;
- polychlorinated biphenyls (PCBs) (*see Polychlorinated Biphenyls*).

The worldwide dimension of the problem is very relevant. For example, the number of potentially contaminated sites in Europe is estimated at approximately 3.5 million with 0.5 million sites being really contaminated and needing remediation [1]. The cost of remediation per site has been estimated between €19 500 and 73 500, with an overall cost for the remediation of all sites around €28 billion. Comparing

these numbers with other countries, e.g., the United States, can be misleading, because estimations greatly change according to the definition of contaminated site. Notwithstanding, it can be reasonably said that the situation is similar in all industrialized countries, and even worse in underdeveloped countries.

Due to the scale of the problem, cleanup of all hazardous waste sites in a short or medium time frame, e.g., 25 years, is not technically and economically feasible. In this context, cleanup interventions should be addressed to the most relevant sites and cleanup goals should be tailored to site-specific conditions.

Within this scope, risk assessment methodologies have been developed. The risk assessment of contaminated sites is a technical procedure to analyze the likelihood and magnitude of adverse effects on human health or the ecosystem due to the direct or indirect exposure to hazardous substances in soil. It is based on characterization of the site and on sound scientific evidence concerning the environmental behavior and toxicity of the contaminants. It follows that this is a retrospective risk assessment, because environmental and human exposure to the contaminants has been occurring. As shown in Figure 1, potential exposure pathways of human beings to hazardous substances in soil or waste include e.g., direct contact, inhalation, ingestion of particles, drinking of contaminated groundwater, etc. Similar exposure scenarios can be described for plants, soil organisms, wildlife, and fishes. In the study of hazardous waste sites, three types of retrospective applications of risk assessment can be operationally distinguished:

1. risk-based ranking of sites at regional scale,
2. screening by application of generic soil quality standards (SQSs),
3. site-specific risk assessment, i.e., the assessment based on specific environmental and exposure conditions at the site.

Generic SQSs are usually based on risk assessment estimates for standard scenarios. When the comparison with SQSs indicates a potential significant risk, the application of a site-specific risk assessment is usually recommended. In the following paragraphs, an overview is given of the risk-based ranking and site-specific risk assessment methodologies. A further insight on risk assessment methodologies to derive generic SQSs is provided in **Soil Contamination Risk**.

Figure 1 Exposure of human and ecological receptors to contaminants (plumes represent contaminant molecules) from hazardous waste sites [Reproduced from [2]. Environmental Protection Agency, 1989.]

Ranking Hazardous Waste Sites

Since the early 1980s, technical procedures have been developed in several countries to rank the hundreds or thousands of hazardous waste sites registered at regional or national levels. One of the most popular systems is the Hazard Ranking System adopted by the United States Environmental Protection Agency [2]. More recently, the European Environmental Agency has collected information about 25 systems worldwide and proposed a new system, named *PRAMS*, to rank areas under risk for soil contamination in Europe [3]. In general, all these procedures are qualitative scoring systems based on source, pathway, and receptor indicators. The source indicator represents the toxic potential of the waste, e.g., toxicity and waste quantity. The pathway indicator represents the likelihood that the hazardous substances are released and transported in the environment. Different pathway indicators can be defined through the soil (direct contact), air, groundwater and surface water media, respectively. The receptor indicators refer to the presence of human or sensitive environments that can be affected by the release. The risk depends on the concurrence of source, pathways, and receptors. Different risk scores can be obtained for each exposure pathway, e.g., on the basis of the product of source, pathway, and receptor indicators. The overall risk score for the site can be derived from the risk scores for all the pathways, by selecting the maximum value or the root mean square of all the scores.

The scoring of each indicator is usually built on structured scoring systems of subtended factors and parameters. For example, in the USEPA's

Hazard Ranking System the source indicator is the sum of two factors, waste characteristics and containment measures, respectively. In turn, the waste characteristics factor depends on parameters like hazardous waste quantity, toxicity, mobility, persistence, and bioaccumulation. For each parameter, scores are defined for quantitative intervals or presence/absence. In case the information is not available, the highest score is generally recommended. Thanks to the capability and widespread use of geographical information system (GIS) technologies, the development of a new spatially resolved ranking system can be foreseen. The integration of ranking systems within GIS allows the proper consideration of spatial correlation among sources and receptors. It also means that the contribution of multiple sources on the same receptors can be identified, as well as the most impacted areas at regional scale.

Site-Specific Risk Assessment

Site-specific risk assessment is based on quantitative modeling of exposure and toxicological effects to estimate the risk for human health or ecological receptors associated with contamination of a specific site. In a reverse application, acceptable risk levels are set to derive acceptable contaminant concentrations, i.e., site-specific remediation goals. The site-specific risk assessment differs from the screening risk assessment, which is applied to standard scenarios to derive general SQSs, in that quantitative modeling is applied to site-specific conditions and, whenever possible, supported by site monitoring.

Thus, in site-specific risk assessment the characterization of the site plays a key role. In the following paragraphs the fundamentals of human health and ecological risk assessment (ERA) for hazardous waste sites are presented.

Human Health Site-Specific Risk Assessment

As mentioned above, characterization of the site is at the very core of the risk assessment. The risk assessment can then be described in four traditional phases: (a) hazard identification; (b) exposure assessment; (c) toxicity assessment; and (d) risk characterization.

Characterization of the Site

The proper characterization of the site is the prerequisite for reliable risk estimates. It should provide a site conceptual model (SCM) and all the data necessary for modeling the fate and the transport of the contaminants [4].

The SCM is a scheme illustrating contaminant distributions, potential or observed released mechanisms, exposure pathways and migration routes and potential receptors. It usually includes maps, cross sections, and diagrams. The development of the SCM is composed of three steps [2]:

1. data gathering on site operation history and development of a preliminary conceptual model of the site;
2. site investigations;
3. refinement of the SCM.

Due to the spatial heterogeneity of the contamination, the definition of effective sampling strategies is a very sensitive issue. A major question is *where* and *how many* samples may be representative of the site contamination. The sampling strategy usually has the objective to detect all the contamination hot spots present at the site. The optimal number of samples may be determined on a statistical basis. In particular, statistical methods able to incorporate available knowledge and expert judgment on the sub-areas that are most likely to contain a hot spot were proven to be more effective and efficient [5, 6]. The use of screening analytical techniques, in particular those supporting real-time results on the field, has

been recently promoted in combination with traditional methods to optimize sampling strategies and reduce spatial uncertainties [7, 8]. The basic idea is that screening methods on the field allow for less sensitive but more dense sampling and to adapt the sampling plan as new information become available (dynamic work strategies) [8].

Hazard Assessment

The objective of hazard assessment is the identification of substances, named *contaminants of concern* (CoCs) present at the site that need to be included in the risk analysis. Since the number of hazardous substances present at the site can be very high, the hazard assessment has also the objective to focus the analysis on a manageable subset of representative CoCs. Scoring systems are traditionally applied. The most popular is that proposed by the United States Environmental Protection Agency [2] and named *concentration-toxicity screening*. It consists of scoring the chemicals according to their concentration and toxicity to obtain a hazard factor HF_{ij} , as follows:

$$HF_{ij} = C_{ij} \times T_{ij} \quad (1)$$

where

HF_{ij} : risk factor for chemical i and medium j

C_{ij} : maximum concentration of chemical i in medium j

T_{ij} : toxicity value for chemical i in medium j .

Separate scores should be calculated for each environmental medium (e.g., soil, groundwater, etc.). Hazard factors are summed to obtain the total hazard factor for all chemicals in a medium and the subset of chemicals accounting for a cumulative percentage of e.g., 99% are retained.

In general, the selection might include additional factors like spread distribution, frequency of detection, mobility, persistence in the environment, chemicals associated with site operation and treatability.

Toxicological Assessment

The objective of the toxicological assessment is the evaluation of the exposure dose–health effect relationship for each contaminant. For the toxicological properties, chronic, subchronic, and acute toxic effects can be distinguished, but in the case of human

exposure to hazardous waste sites the chronic exposure is usually the most relevant. Threshold and nonthreshold effects are distinguished. For threshold effects contaminants, an exposure dose below which adverse effects are negligible can be derived. The toxicity is expressed by human health reference doses (RfD) ($\text{mg/kg}_{\text{body weight}^{-\text{day}}}$) derived on the basis of toxicological tests data (i.e., no observed adverse effect levels or benchmark doses) and uncertainty/assessment factors. In the case of nonthreshold effects substances, e.g., genotoxic carcinogens, it is assumed that even at very low levels of exposure residual risk cannot be excluded. The toxicity is expressed by potency factors, i.e., estimated incremental incidence of cancer versus daily intake in a lifetime [$\text{mg/kg}_{\text{body weight}^{-\text{day}}}$] $^{-1}$. Different potency factors and RfDs can be estimated for oral, inhalation, and dermal exposure routes.

Reference doses and potency factors have been derived for the most common contaminants by national and international competent authorities. Popular sources of toxicity data available on the web are the integrated risk information system (IRIS, <http://www.epa.gov/iris>) managed by the United States Environmental Protection Agency, and the risk assessment information system (RAIS, <http://rais.ornl.gov/>) managed by the United States Department of Energy (DoE).

Exposure Assessment

The exposure analysis represents the core of risk assessment. The objectives are the quantification of the magnitude (exposure concentration), frequency, duration and routes of exposure. Three steps can be defined. The first step is characterization of the exposure setting [2]. Basic site characteristics, such as climate, vegetation, groundwater hydrology, and the presence and location of surface water are identified in this step. Potentially exposed populations are identified and their vulnerability is described in terms of e.g., distance from the site, activity patterns, and the presence of sensitive subpopulation groups. The future use of the site and exposed populations should also be considered. The second step is identification of exposure pathways. Exposure diagrams are usually developed that indicate contamination sources, release mechanisms, transports medium, exposure routes and receptors. Exposure scenarios can be

referred to the worker, the trespasser, the residential user, the recreational user, and the constructions on the site. The third step is quantification of the exposure, which comprises the estimation of exposure concentrations and the calculation of intakes. Given the exposure concentration, the administered dose (intake) can be calculated by the following general equation:

$$I = \frac{(C \times CR \times EF \times ED)}{(BW \times AT)} \quad (2)$$

where

I : intake ($\text{mg/kg}_{\text{body weight}^{-\text{day}}}$)

C : concentration at exposure point (e.g., mg l^{-1} in water or mg m^{-3} in air)

CR : contact rate (e.g., 1 day^{-1} or $\text{m}^3 \text{ day}^{-1}$)

EF : frequency (day yr^{-1})

ED : exposure duration (years)

BW : body weight (kg)

AT : average time (days).

This equation is modified for specific exposure pathways, by including factors such as the rate of respiration for inhalation or the amount of skin exposed for dermal contact. The transport processes that are commonly modeled in human exposure assessment to hazardous waste sites are represented in Table 1. A broad range of fate and transport models is available in a number of software packages. If refined estimation of the exposure is needed, a tiered approach is recommended which starts from application of conservative simple modeling, like steady-state equilibrium equations, and moves to more complex models, like numerical and probabilistic models. Among the simpler modeling tools, the algorithms proposed for petroleum release sites by the American Society of Testing and Materials have encountered a wide popularity [9]. It is important to consider that exposure modeling requires a wide range of site characterization and chemical-specific data, other than exposure data. The list of input values in fate and transport modeling might include more than 60 parameters in the following categories:

- compound-specific physicochemical properties;
- meteorological parameters;
- surface parameters;
- hydrogeological parameters;
- characterization of buildings at the site;
- human receptors parameters.

Table 1 Cross-media transfers, transport and fate and intake routes commonly modeled in the assessment of human exposure at hazardous waste sites

Source	Cross-media routes	Transport and fate	Intake routes
<u>Direct exposure pathways</u>			
Surface soil	–	–	Ingestion of soil Dermal exposure
<u>Air exposure pathways</u>			
Surface soil	Volatilization and particulate emission	Air dispersion	Ambient air inhalation of soil vapors and soil derived dust. Dermal exposure to dust
Subsurface soil	Volatilization	Air dispersion	Ambient air inhalation of soil vapors
Subsurface soil	Enclosed space volatilization	–	Indoor inhalation of soil originated vapors
Groundwater	Volatilization	Air dispersion	Ambient air inhalation of soil vapors
Groundwater	Enclosed space volatilization	–	Indoor inhalation of soil originated vapors
<u>Groundwater exposure pathways</u>			
Soil	Leaching to groundwater and dilution	Groundwater dispersion, transport and attenuation	Groundwater ingestion: inhalation of volatilized domestic water, showering (dermal contact and inhalation)
<u>Diet exposure</u>			
Soil (e.g., contaminated from run off)	Uptake of homegrown vegetables and fruits	–	Consumption of homegrown vegetables (and attached soil), fruit, meat, dairy products
<u>Surface water exposure</u>			
Soil	Leaching to groundwater, contact with surface water and dilution	Transport in the unsaturated zone, groundwater dispersion, transport, and attenuation	Dermal contact and water ingestion while swimming, consumption of fish and shellfish

Risk Characterization

This phase combines the results of the exposure analysis and the toxicological assessment. The risk for threshold effects contaminants is defined as the quotient of the estimated intake dose to the RfD, also named the *hazard index*. The risk for nonthreshold effect contaminants (e.g., carcinogenetic) is defined as the chronic daily intake dose multiplied by the carcinogenic potency factor. The result is the lifetime incremental risk associated with exposure to the hazardous waste site. The calculated (incremental)

risk can be compared to the risk caused by a variety of other sources, such as accidents, cigarette smoking, etc.

If acceptable risk thresholds are defined, reverse calculation allows for derivation of contaminant concentrations at the site below which the risk is considered not relevant. These concentration thresholds can be used as remediation goals. Acceptable risk thresholds are usually taken as the hazard index equal to 1 for threshold effects contaminants and the incremental lifetime risk between 10^{-6} and 10^{-4} for nonthreshold effects contaminants. However, the

acceptable risk thresholds should not be regarded as quantitative statements about risk, i.e., cancer affecting one person in 1 million. They should be considered conventional and operational indicators of “negligible risk” closely related to the extent of the conservative assumptions adopted in the risk estimation [10].

Risk characterization should always be supported by estimation of related uncertainties. Epistemological uncertainty, those related to ignorance about a poorly characterized variable or phenomenon, and uncertainty associated with the intrinsic variability of the variable or phenomenon, are usually considered together. However, they should be distinguished to the extent possible, because they have different implications in risk assessment: epistemological uncertainty is reducible by further measurements or studies, whereas variability is not. Uncertainty regards models assumptions and prediction capabilities as well as model input values. Uncertainty related to model input values can be quantified by probabilistic methods, like multilevel interval analysis, Monte Carlo and Latin hypercube simulations. Monte Carlo simulation implies the description of input parameters by means of probability distribution functions and the generation of a probability distribution of risk estimation.

Risk assessment of hazardous waste sites is usually a stepwise approach: it starts from conservative assumptions to verify if site conditions satisfy the criteria for a quick regulatory closure or warrant a more site-specific and accurate, but also more expensive and time consuming, risk characterization. The appropriate, i.e., cost-effective, level of investigation and modeling depends on the complexity of the site and remediation costs.

Site-Specific Ecological Risk Assessment

Historically, at hazardous waste sites the ecological concern has been second to the human health concern. Nevertheless, in particular where large areas are involved and ecologically sensitive environments are affected, ecological considerations can play a driving role in the definition of remediation interventions (see **Ecological Risk Assessment**). This is often the case of mining waste sites or in proximities of surface water bodies (see **Water Pollution Risk**). The USEPA guidance for the application of ERA to hazardous waste sites [11] defines a three-phase process,

i.e., (a) problem formulation, (b) stressor response and exposure analysis, and (c) risk characterization. Essential for all steps are negotiation and agreement of the need for further action between the risk assessor, the risk manager and other stakeholders.

In ERA, effect assessment is more complex than for human health risk assessment. This is mainly because protection of the terrestrial ecosystem would impact multiple species and their relations with the abiotic environment. In the scope, toxicity effects to the microbial community, plants and soil fauna are usually considered, but it is rather difficult to predict effects to the population, community and ecosystem levels, as well as impairments to soil functioning. In general, a simplification is adopted which consists of identification of specific assessment endpoints. Assessment endpoints are explicit expressions of the actual environmental value that is to be protected. Two elements are required to define assessment endpoints. The first is identification of the specific valued ecological entity. This can be a species (e.g., earthworms like *Eisenia andrei* or specific plants), a functional group of species (e.g., soil dwelling organisms), a community (e.g., soil fauna), an ecosystem, a specific habitat or others. The second is the characteristic about the entity that is important to protect and is potentially at risk (e.g., density of soil dwelling organisms). Criteria for the selection of assessment endpoints are their ecological relevance, their susceptibility to potential stressors and relevance to management goals.

Major uncertainties in ERA (see **Ecological Risk Assessment**) are the extrapolation of ecosystem relevance of selected assessment endpoints, the modeling of exposure and effects, the inclusion of factors like bioavailability and biomagnifications. In order to deal with conceptual uncertainties in a pragmatic way, it has been proposed that weight of evidence approaches be used. The rational is that many independent ways to arrive at one conclusion will provide a stronger evidence for ecological effects, making ERA less uncertain [12]. In the so-called TRIAD approach, three lines of evidence about ecological impairments associated with the contamination can be defined [13]:

- chemical, i.e., the concentration of chemicals, their bioavailability and bioaccumulation;
- eco-toxicological, i.e., results of bioassays carried on site samples;

- ecological, i.e., field ecological observations at the contaminated site.

Risk Management

It should be borne in mind that contamination of the soil is not only an issue of human and environmental health, but also a barrier to the redevelopment of the sites. This close connection between environmental and redevelopment problems is at the core of risk management. The benefits associated with the reuse of the site are often the main driver of detailed risk assessment and remediation interventions. Risk-management strategies can be based on the elimination or reduction of the hazardous waste source, or the control of exposure pathways or receptors. Besides the technical estimation of the risk, the perception and societal value of the risk play an utmost important role. For this reason, risk communication strategies are relevant aspects of risk management. Decision support systems have been developed to compare environmental and socioeconomic benefits and drawbacks behind different remediation options [14, 15].

Environmental Risks

Hazards Insurance: A Brief History

Long before the development of insurance as such, early civilizations evolved various kinds of insurance-like devices for transferring or sharing risk. For example, early trading merchants are believed to have adopted the practice of distributing their goods among various boats, camels, and caravans, so each merchant would sustain only a partial loss of his goods if some of the boats were sunk or some of the camels and caravans were plundered. This concept survives today in the common insurance practice of avoiding overconcentration of properties in any one area, and by spreading risk through reinsurance arrangements (see **Reinsurance**).

As long ago as the Code of Hammurabi in 1950 B.C., commercial shipping included the practice of bottomry, whereby a ship's owner binds the vessel as security for the repayment of money advanced or lent for the journey. If the ship is lost at sea, the lender loses the money, but if the ship arrives safely, he receives both the loan repayment and a premium, specified in advance, which exceeds the legal rate of interest. Bottomry is one of the oldest forms of insurance, and was used throughout the ancient world [1]. By 750 B.C., the practice of bottomry was highly developed, particularly in ancient Greece, with risk premiums reflecting the danger of the venture. Mutual insurance also developed at this time, whereby all parties to the contract shared in any loss suffered by any trader who paid a premium.

The decay and disintegration of the Roman Empire in the fifth century A.D. was followed by the development of small, isolated, self-sufficient, and self-contained communities. Since international commerce practically ceased, there was little need for sophisticated risk-sharing devices such as insurance. However, the revival of international commerce in the thirteenth and fourteenth centuries revitalized use of insurance-type mechanisms. In England, Lloyd's Coffee House provided a gathering place for individual marine underwriters, leading to the formation of Lloyd's of London in 1769. London then became the center of the global marine insurance market.

Emergence of Fire Insurance

Modern fire insurance was developed after the Great Fire of London in 1666 destroyed over three quarters of the city's buildings. In the early eighteenth century, Philadelphia took the first steps toward the protection of property from the fire peril; the city possessed seven fire-extinguishing companies. Philadelphia also passed regulations concerning the nature and location of buildings in the city. Led by Benjamin Franklin, Philadelphians organized the first fire insurance company in America, the Philadelphia Contributionship for the Insurance of Houses from Loss by Fire. It was followed by the creation of four more insurance companies before the end of the eighteenth century, and by an increasing number of fire insurance companies in other cities in the first half of the nineteenth century. The financial problems associated with catastrophic losses are well illustrated by the great New York fire of 1835, which swept most of the New York fire insurance companies out of existence.

Conflagrations such as the great New York fire of 1835 and the Chicago fire of 1871 focused attention on fire prevention over other natural hazards. Established in 1866, the National Board of Underwriters in New York City concentrated on protecting the interests of fire insurance companies by establishing safety standards in building construction and working to repress incendiarism and arson. In 1894, fire insurance companies created the Underwriters Laboratories as a not-for-profit organization to test materials for public safety. Founded in 1896, the National Fire Protection Association still plays a major role in reducing the number of fires by encouraging proper construction. Today's engineering and technical schools conduct research and educate and train fire safety personnel.

Factory Mutual Insurance Companies Provided Incentives and Standards for Improved Risk Management

As an important ingredient for risk spreading and risk reduction, insurance is exemplified by the factory mutual insurance companies founded in the early nineteenth century in New England. These companies offered factories an opportunity to pay a small premium in exchange for protection against potentially large losses from fire, reflecting the risk spreading

objective of insurance. The mutuals also required inspections of factories both before and after issuing a policy. Poor risks had their policies canceled, and premium reductions were given to factories that instituted loss prevention measures.

For example, the Boston Manufacturers worked with lantern manufacturers to encourage them to develop safer designs and then advised all policyholders that they had to purchase lanterns from those companies whose products met their specifications. In many cases, insurance would only be provided to companies that adopted specific loss prevention methods. For example, one company, the Spinners Mutual, only insured risks where automatic sprinkler systems were installed. The Manufacturers Mutual in Providence, Rhode Island, developed specifications for fire hoses and advised mills to buy only from companies that met these standards [2].

Wind Damage and the Rise of Extended Coverage

Insurance against wind damage was first written in the second half of the nineteenth century, but only by a limited number of companies. In its earliest form, the policy contract provided for insurance against loss by fire or storm. Until 1880, this type of insurance was sold by local or farmers' mutual insurance companies on rural risks, rather than city risks, and was confined to the East. The first insurance covering windstorm by itself was initiated in the Midwest and was called *tornado insurance*. It continued as a separate policy until 1930.

Windstorm insurance began to evolve in its present form in 1930 when the stock fire insurance companies filed an "Additional Hazards Supplemental Contract" in conjunction with the standard fire policy. This new contract provided a single rate for coverages that had traditionally been offered as separate policies for tornado, explosion, riot and civil commotion, and aircraft damage insurance. Incorporating this array of coverage in one contract was seen as a radical step in a generally conservative industry. In October 1930, the contract was expanded even further when the New England Insurance Exchange revised it to include perils from hail and motor vehicles, as well as all types of windstorms, not just tornadoes. In 1938, the Additional Hazards Supplemental Contract was renamed as *extended coverage* (EC), and smoke damage was added to the coverage.

When it was introduced in the East, the EC endorsement was at first purchased by few individuals, and was viewed as a luxury. Comparatively little of this insurance was sold in Massachusetts until after the 1938 hurricane, the first to hit New England in a century. This event stimulated sale of the EC endorsement in part, because many banks then required that it must be added to fire insurance on mortgaged property. Although there were some changes in the perils covered during the 1930s and 1940s, the basic package has been retained and continues to be used today [3].

Property-Casualty Insurance Today

The insurance industry today is divided into two broad areas: property-casualty insurance companies, and life and health insurance companies. Property-casualty companies predominate, with close to 4000 property-casualty companies and about half as many life insurers operating in 1992. The insurance laws of the various states recognize the sharp distinction between these different types of insurance. The property-casualty companies are the main source of coverage against natural hazards in the United States and hence bear most of the insured losses from disasters.

There is a significant difference between the property and casualty lines, although both are written by property-casualty companies. Property insurance reimburses policyholders directly for their insured losses, and thus is labeled as *first-party coverage*. Casualty insurance, for the most part, protects its policyholders against financial losses involving third parties, and consequently is called *third-party insurance*. For example, an automobile liability policy typically pays for damage caused by negligent action on the part of its insured that involves a vehicle owned by a third party. Other important casualty lines of insurance are those of general liability and workers' compensation.

Agents or brokers sell most insurance policies. An agent legally represents the insurer and has the authority to act on the company's behalf. In property insurance, independent agents can represent several companies, while exclusive agents represent only a single company. Insurance is also marketed by direct writers, who are employees of the insurer, and by mail-order companies. The emergence of

electronic commerce is making the World Wide Web an increasingly important source for marketing insurance. Brokers legally represent the insured, normally a corporation. They play a key role in commercial property insurance today, providing risk management and loss control services to companies as well as arranging their insurance contracts (*see also Nonlife Insurance Markets; Risk Classification in Nonlife Insurance*).

Health Hazards Posed by Dioxin

Since the late 1970s, regular meetings of international groups of scientists from nearly every developed country have been convened to discuss the developing scientific evidence on 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) exposure and toxicity (the 1986 Banbury Conference, and the Annual International Symposium on Halogenated Environmental Organic Pollutants and POPs). Most recently, a rodent cancer bioassay evaluating TCDD and 2,3,4,7,8-pentachlorodibenzofuran (PeCDF) has been completed [1] with alternative potency estimates made [2–4]; tolerable intake estimates have been established by several groups [5–8]; and several cancer potency estimates based on occupational epidemiology studies (*see Occupational Cohort Studies*) have been proposed [9–17, 18].

Hazard Identification

Hazard identification is the process of evaluating the available toxicity studies and determining the range of toxic endpoints relevant to humans, as well as identifying any significant data gaps relating to the primary studies relied upon in the derivation of the toxicity criteria (e.g., cancer potency factor or reference dose (RfD)) [19].

Noncancer Hazard at Low Doses

There are dozens of studies that address the toxicology or epidemiology of TCDD and some dioxin-like compounds [20–34]. Animal studies demonstrate a relatively diverse range of dose-dependent noncarcinogenic adverse responses to TCDD that vary considerably between species including wasting syndrome, reproductive toxicity, developmental effects, and commonly observed toxic effects on the liver, kidney, gastrointestinal tract, and certain endocrine organs [21, 34]. Chloracne has been observed in studies of humans with excessive exposure to TCDD from occupational or accidental contact [35–37]. Clinical tests have suggested subtle changes of metabolism, endocrine function, and developmental effects in humans [26, 33, 38], but such effects have not been

conclusively demonstrated at the low concentrations to which humans are routinely exposed.

Research organizations, regulatory agencies, and individual scientists have relied on measures of different kinds of toxicity to determine “safe” exposure levels. In general, scientists examine the toxicologic literature, identify the adverse effect relevant to humans that occurs at the lowest dose (*see Low-Dose Extrapolation*), and calculate the likelihood that adverse effect will occur at various exposure levels. For instance, Agency for Toxic Substances and Disease Registry (ATSDR) scientists relied upon developmental studies in rodents and monkeys to set its intermediate duration and chronic minimal risk levels (MRLs). ATSDR relied upon immunological toxicity studies in guinea pigs [39] for their intermediate MRL and developmental toxicity studies in monkeys [40] for their chronic MRL.

In a review of the TCDD literature concerning noncancer effects in animals and humans, Greene *et al.* [41] identified chloracne in children exposed during the Seveso trichlorophenol reactor explosion incident [42–46] as the best documented and lowest-dose disease endpoint in humans. Greene *et al.* [41] also identified developmental studies of TCDD as providing the best documented and lowest-dose toxicity endpoint in animals [41, 47–53]. Scientists at the World Health Organization [54] and the Joint FAO/WHO Expert Committee on Food Additives [31] relied on these same developmental toxicity studies to derive their tolerable intake estimates for TCDD. These scientists, like Greene *et al.* [41], believed their estimates of tolerable intake for the noncancer effects of TCDD would place the cancer hazard at negligible or tolerable levels [31]. WHO [31] identified tolerable estimates of intake for toxicity equivalents (TEQ) in the range of $1\text{--}5\text{ pg kg}^{-1}\text{ day}^{-1}$.

Interestingly, after a very long and exhaustive analysis, the United Nations working group on polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs) reached the conclusion that doses in the current Western diet should not be expected to produce adverse health effects [55]. The current average intake of dioxin/furan TEQ in the United States diet is about $1\text{--}3\text{ pg kg}^{-1}\text{ day}^{-1}$ [31, 34]. Conversely, the US EPA has stated that they believe background doses due to diet for Americans are potentially hazardous [18]. A peer review of the so-called EPA reassessment of dioxin (a nearly 20-year-old process) by the

National Academy of Science within the United States recommended that the EPA update their current view of this chemical and place greater weight on describing the uncertainty in their predictions regarding the significance of the current risk of dietary exposure [56].

Cancer Hazard at Low Doses

TCDD has long been known as one of the most potent rodent carcinogens among the chemicals regulated by US EPA. Different researchers and regulatory scientists have calculated the cancer potency of TCDD to range from 40 to 1 400 000 (mg/kg/day)⁻¹ based on findings from the same animal study by Kociba *et al.* [57]. This 2-year cancer bioassay, which involved dietary ingestion of TCDD by rats, has been the basis for most of the published cancer potency estimates for TCDD and for the other 2,3,7,8-substituted PCDD/Fs (*via* the TCDD toxic equivalents approach) [58]. Different interpretations of the data correspond to use of different assumptions about mechanism of action (e.g., nongenotoxic or genotoxic), endpoints to be modeled (e.g., neoplastic nodules *versus* tumors *versus* carcinomas) and extrapolation models (e.g., linearized multistage *versus* safety factor approach) [59]. Recent developments include a further evaluation of the cancer potency of TCDD and 2,3,4,7,8-PeCDF in a chronic rodent bioassay [1], and proposals from US EPA [34] and others [9, 10, 12, 13] rely on occupational cancer epidemiology studies to define PCDD/F cancer potency.

International Agency for Research on Cancer (IARC) [20] evaluated the epidemiological literature on TCDD, noting the generally low magnitude of increased risk, the absence of any consistent pattern of site-specific cancer excess, and the lack of clear dose-response trends. The IARC workgroup classified TCDD as “carcinogenic to humans (Group 1)” on the basis of this limited epidemiological evidence, sufficient animal evidence, and the fact that the presumed mechanism (Ah receptor activation) is known to occur in humans and experimental animals. However, a direct correlation between Ah receptor binding affinity and cancer response has not been clearly demonstrated in animals or humans for TCDD and other PCDD/Fs, and significant quantitative and qualitative differences between humans and animals almost certainly exist [60].

The US EPA Science Advisory Board (SAB) that reviewed the US EPA “reassessment” in 2000 was fundamentally undecided about whether the available evidence was sufficient for TCDD to be considered a human carcinogen at any dose; at least half of the members concluded that the evidence was inadequate to support a “known human carcinogen” designation [61]. This group within the SAB offered several lines of support for its views. One included an analysis that reported that only 2 of the 12 key cohort studies (*see Cohort Studies*) had significantly elevated total cancer mortality rates, and there was a flat dose-response trend (i.e., no dose-response relationship) when cancer rates were plotted against average body burden level for the various cohorts [24, 30]. Moreover, several groups of workers who had chloracne (which likely requires peak blood lipid TCDD levels above 5000 ppt; [41]) did not have an increased cancer risk [62]).

Recent papers put into question the scientific foundation for US EPA’s use of worker epidemiology studies to define their proposed TCDD cancer potency factor of 1 000 000 (mg/kg/day)⁻¹ [63]. Aylward *et al.* [63] showed (as others have suggested in the past) that the human half-life of TCDD is much shorter at high dose levels, on the basis of a pharmacokinetic model of TCDD elimination in exposed Seveso residents and workers exposed to high levels of TCDD in a laboratory accident. This finding is significant because it invalidates the assumption in each of the epidemiology-based dose-response analyses (*see Dose-Response Analysis*) that body burdens of workers can be calculated using a constant half-life for TCDD. Aylward *et al.* [63] correctly note that if the TCDD half-life is shorter at high body burdens, determinations of dose based on calculations that incorporate a constant half-life are underestimated (and potency is thereby overestimated). This has enormous implications in the derivation of a cancer slope factor from these occupational studies. Until the half-life issue is addressed for these occupational cohorts, it doesn’t seem appropriate to these cancer potency estimates in quantitative risk assessments of TCDD.

PCDD/Fs are generally found in environmental media as chemical mixtures, and thus, humans are more likely exposed to mixtures rather than individual congeners. This is an obvious complication of the classic risk assessment paradigm because detailed dose-response studies are largely limited to TCDD.

To address this challenge, toxicity equivalency factors (TEFs) were developed to facilitate the quantification of PCDD/F dose and potential health risks. TEFs are relative potency factors assigned to each dioxin-like chemical to approximate the total mixture potency relative to the well-studied and reasonably well-understood toxicity of TCDD in experimental animals. The process involves assigning individual TEFs to each of the 17 2,3,7,8-chlorinated congeners. There is a scientific consensus on the general mechanism through which these congeners begin to exert their effects e.g., they first bind with the Ah receptor in the cytosol of a cell, the receptor–ligand complex then moves to the nucleus of a cell where it binds to dioxin response elements in the regulatory portion of genes. This concept is reflected in the current regulatory approach which relates the potency of other 2,3,7,8-substituted congeners to TCDD in comparable tests (TCDD, by definition, has a TEF of 1). The other 2,3,7,8-substituted congeners have TEF values ranging from 1 to 0.0001. Congeners without 2,3,7,8-substitution have been assigned TEF values of zero and are therefore not included in the analysis of TEQ. The most current TEF values were recently reported by the WHO following re-evaluation of the 1998-TEF values [64]. Despite a broad scientific consensus that use of this approach for risk assessment purposes is appropriate, there are substantial data gaps and scientific uncertainties associated with the use of the TEF approach [65, 66]. As such, some investigators have proposed utilizing distributions of relative potency values rather than point estimate TEFs [66, 67].

Although TCDD is the most widely studied of the PCDD/Fs, many studies have examined the toxicological properties of other congeners. The common underlying mechanism of action for all dioxin-like compounds is assumed to be that the chemical first binds to the Ah receptor [34, 58, 68, 69]. This assertion has been widely adopted for regulatory purposes to implicate all of the PCDD/Fs as multiorgan toxicants even though the evidence remains limited as to whether the non-TCDD congeners exhibit the same broad range of effects as TCDD. For example, IARC [20] concluded that there is sufficient evidence in animals and humans to designate TCDD as “carcinogenic to humans (Group 1)”, while all other PCDDs and PCDFs are “not classifiable as to their carcinogenicity to humans (Group 3)”. There is limited but growing evidence to support the assumption that other 2,3,7,8-substituted congeners have the capacity

to cause the effects that have been documented in animals treated with TCDD [2, 30, 70, 71]. However, the receptor-mediated mechanism of action for TCDD is subject to competitive inhibition by other dioxin-like congeners as well as other environmental chemicals with varying degrees of Ah receptor affinity [24, 27, 65, 69, 70, 72–79]. The potential impact of such inhibition should not be discounted, especially at low environmental doses at issue for risk assessment.

Others have suggested that tumor rates below control levels in the lowest TCDD dose group of the [57] study may indicate competitive inhibition of TCDD-induced response and/or a hormetic effect, i.e., depression of background cancer response at very low doses [61, 80–82]. Thus, the net effect of the usual low level exposure of humans to mixtures of dioxin-like compounds in the environment may present a much smaller human health hazard than that indicated by linear extrapolation models applied to animal studies of TCDD alone.

Noncancer Hazard Assessment

A number of different estimates of the so-called safe dose for noncancer effects have been published by regulatory agencies and other researchers over the past 20 years concerning PCDD/Fs. Table 1 provides a summary of the noncancer toxicity criteria that have been published since 1983. Most these estimates fall in the range of $1\text{--}5\text{ pg kg}^{-1}\text{ day}^{-1}$.

US EPA had previously established a noncancer RfD of $1\text{ pg kg}^{-1}\text{ day}^{-1}$ for TCDD. This value was withdrawn in 1989 and has now been replaced with a “margin of exposure (MOE)” approach which examines the source-related contribution to daily dose and/or body burden in comparison to background exposures and/or other no-effect-level or low-effect-level dose benchmarks [34, 83]. US EPA currently asserts that an appropriately defined RfD for TCDD would be of no practical benefit because this “safe” dose would fall below background exposure levels (i.e., below daily intake in the foods of those in western society who have no unusual source of exposure) [84]. For example, based on Portier [68], estimates of the effective dose (ED) of TCDD at 1% effect incidence (ED_{01}) are as low as $0.013\text{ pg kg}^{-1}\text{ day}^{-1}$; this corresponds to a steady-state human body burden of 0.025 ng kg^{-1} (ng of TCDD/kg of body weight). Following a trend of decrease over the past two decades,

Table 1 Procedures used by regulatory agencies or scientific bodies to estimate virtually safe or tolerable doses for humans based on dose–response data for noncancer effects of TCDD

Agency/group	Basis for extrapolation to humans	Acceptable intake rate
Japan, 1983 [84]	Yusho disease NOAEL in humans (1 ng kg ⁻¹ day ⁻¹) with 10-fold safety factor for sensitive humans	100 pg kg ⁻¹ day ⁻¹
Germany, 1985 [84]	Reproductive toxicity NOAEL = 1 ng kg ⁻¹ day ⁻¹ [94] with safety factor of 100–10000	1–10 pg kg ⁻¹ day ⁻¹
Nordic Group, 1987 [85]	Reproductive toxicity NOAEL = 1 ng kg ⁻¹ day ⁻¹ [94] with safety factor of 100	10 pg kg ⁻¹ day ⁻¹
United States, 1989 [86]	Reproductive toxicity NOAEL = 1 ng kg ⁻¹ day ⁻¹ [94] with safety factor of 1000	<i>RfD</i> = 1 pg kg ⁻¹ day ⁻¹
World Health Organization, 1990 [87]	Combined consideration of cancer, liver toxicity, reproductive and immune toxicity NOAELs = 1 ng kg ⁻¹ day ⁻¹ with 100-fold safety factor. Also adopted by UK, New Zealand, and the Netherlands	10 pg kg ⁻¹ day ⁻¹
United States, 1992 [88]	Reproductive toxicity NOAEL = 1 ng kg ⁻¹ day ⁻¹ [94] with 1000 safety factor for chronic/intermediate minimal risk level (MRL)	Chronic MRL = 1 pg kg ⁻¹ day ⁻¹ Intermediate MRL = 1 pg kg ⁻¹ day ⁻¹
The Netherlands, 1996 [89]	Reproductive toxicity LOAEL = 0.1 ng kg ⁻¹ day ⁻¹ in monkey studies with 100-fold safety factor	1 pg kg ⁻¹ day ⁻¹
Japan, 1997 [90]	Combined consideration of reproductive toxicity in monkeys [95] and carcinogenicity	5 pg kg ⁻¹ day ⁻¹
ATSDR, 1998 [22, 23, 91, 92]	Chronic MRL: Reproductive toxicity in monkeys with 120-fold safety factor applied to LOAEL [40] Intermediate MRL: 90-day immunotoxicity study in guinea pigs with 30-fold safety factor [39]	Chronic MRL = 1 pg kg ⁻¹ day ⁻¹ Intermediate MRL = 20 pg kg ⁻¹ day ⁻¹
U.S. EPA, 2000 [68]	ED-01 body burden of 0.025 ng kg ⁻¹ in rats based on [47] sperm effects, converted to human daily dose assuming 50% bioavailability and 7.6-year half-life	0.013 pg kg ⁻¹ day ⁻¹ margin of exposure approach: < 0.1 pg kg ⁻¹ day ⁻¹ including background
World Health Organization, 2000 [54]	Reproductive toxicity in rats with 10-fold safety factor applied to LOAEL [48, 49, 96, 97] calculated from maternal body burden with half-life of 8.5 years	Tolerable daily intake: 1–4 pg kg ⁻¹ day ⁻¹
European Commission, 2001 [93]	Reproductive toxicity in rats with 9.6-fold safety factor applied to NOAEL for male rat offspring [51, 53] calculated from maternal body burden with half-life of 7.6 years	Tolerable weekly intake: 14 pg/kg/week or 2 pg kg ⁻¹ day ⁻¹
United Kingdom, 2001 [8]	Reproductive toxicity in rats with 9.6-fold safety factor applied to NOAEL for male rat offspring [51] calculated from maternal body burden with half-life of 7.5 years	Tolerable daily intake: 2 pg kg ⁻¹ day ⁻¹
World Health Organization (JECFA), 2001 [31]	Reproductive toxicity in rats with 9.6-fold safety factor applied to NOAEL for male rat offspring [51, 53] calculated from maternal body burden with 7.6-year half-life.	Provisional tolerable monthly intake: 70 pg/kg/month or 2.3 pg kg ⁻¹ day ⁻¹

current background human body burdens of TCDD appear to average around 3 ppt in blood lipid or about 0.75 ng/kg of body weight for a 60-kg person with 25% body fat, with total lipid TEQ from PCDD/Fs being about 15 to 30 from a public health to set an RfD that is well below average body burdens of TCDD and total TCDD toxic equivalents for the general public.

The issue of background dietary exposures becomes a potentially important concern for defining a proper noncancer toxicity criterion. The RfD criterion is defined as a safe dose level determined by taking a no-effect level or a low-effect level defined in human or animal studies and dividing that level by appropriate safety/uncertainty factors to arrive at a conservative level that can be compared to doses received from a particular source, e.g., contaminated soils in a residential area.

US EPA [34] asserts that the low-effect levels observed in certain animal studies could plausibly occur at PCDD/F body burdens within 10- to 100-fold of the TEQ average in the background population. However, there is no confirmation that humans experience such effects, even in studies of humans with much higher body burdens. Several reviewers have pointed to the inconclusive nature of the studies that US EPA [98] cited as evidence of human effects of PCDD/Fs at doses or body burdens near background levels [22, 23, 25, 26, 28, 30, 32, 33, 38, 99]. The absence of findings confirming excess disease in humans at or near background body burdens may reflect the difficulties in finding proper control (unexposed) populations to distinguish them. However, it seems equally likely that, given the limited range of toxicity in humans at very high doses, alternative explanations may apply to risks at or near background body burdens of PCDD/Fs. These may include the following:

1. Humans may be less sensitive compared with test species in regards to experiencing the adverse effects under study.
2. The steady-state body burden of TCDD may not be an appropriate dose metric for comparisons between these animal studies and humans.
3. Studies of TCDD alone in animals may not be representative of the human population which experiences predominant exposures to PCDD/F mixtures of which TCDD is only a small fraction (e.g., competitive inhibition of Ah receptor).

4. It may not be possible to extrapolate higher-dose studies in animals to humans in a meaningful way because of a combination of factors which may include nonlinear (threshold-dependent) dose-response relationships, predominant influences of competitive inhibition of Ah receptor activation from environmental mixtures [78], and/or hormetic effects of background environmental exposures in humans [82] that do not occur at higher/TCDD-only doses in animals.

Regardless of these considerations, the US EPA withdrew its original RfD of $1 \text{ pg kg}^{-1} \text{ day}^{-1}$ for TCDD and proposed a MOE approach as an alternative to evaluating noncancer risks. The MOE is calculated by dividing a “point of departure” for extrapolation purposes at the low end of the range of observation in human or animal studies (e.g., the ED_{01}) by the human exposure or body burden of interest (predicted dose). They propose that MOE values in excess of 100–1000 for background plus site-related TEQ doses “are adequate to rule out the likelihood of significant effects occurring in humans based on sensitive animal responses or results from epidemiologic studies”. However, the practical application of this approach is hampered by many variables and uncertainties that will potentially take many years to sort out, including the reliable estimation of background exposures and the validity of many possible choices for the “point of departure” to be assessed [100–102]. Others have proposed that pharmacokinetic models similar to those used for risk assessment of lead exposures may be appropriate for dioxin-like compounds [103, 104]. MOE analysis was not done in this assessment, instead practical surrogate values for TCDD RfD were used to evaluate noncancer hazard.

International regulatory authorities have expressed noncancer toxicity criteria as tolerable daily intake (TDI) [54], tolerable weekly intake (TWI) [93], or provisional tolerable monthly intake (PTMI) [31] expressed as a single value or a range (Table 1). These values are based on scientific panel reviews of the currently available literature on TCDD and other PCDD/Fs. These tolerable intake estimates are considered by these authorities to be protective against cancer and noncancer health effects of PCDD/Fs.

ATSDR’s estimated safe dose for noncancer effects of TCDD consider duration of exposure. ATSDR has established acute, intermediate, and

chronic MRLs. An MRL is defined as “an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer effects over a specified duration of exposure”. The scientific basis for prior TCDD MRLs [88] and current MRLs [21] has been reviewed previously [22, 23]. The MRL values for acute ($200 \text{ pg kg}^{-1} \text{ day}^{-1}$) and intermediate ($20 \text{ pg kg}^{-1} \text{ day}^{-1}$) exposures are higher now (less conservative) than they were on the basis of the available studies in ATSDR’s earlier assessment [88]. Indeed, the current MRL for intermediate oral exposures is 20-fold higher than the 1992 value, whereas the chronic MRL ($1 \text{ pg kg}^{-1} \text{ day}^{-1}$) remained consistent with the former chronic MRL and the former US EPA RfD for TCDD [105]. ATSDR explained that these MRL changes are the result of greater availability of human studies and animal studies that addressed certain uncertainties in the earlier MRL determinations [22, 23]. This reduced uncertainty translated into plausible justifications for the use of smaller safety margins on the MRL [22, 23, 32].

Closing

All in all, in spite of the hundreds of millions of dollars in research devoted to studying PCDD/PCDFs over the past 30 years, the ability of the scientific community to quantitatively characterize the risks to humans of current environmental doses is not nearly as certain as one would expect. The precise mechanism through which the chemical acts in humans is still not well understood and the role of other chemicals that compete for the Ah receptor remains unclear with respect to predicting both the cancer and non-cancer risk at very low doses. One is hard pressed to identify another chemical which has been so difficult to characterize in the history of toxicology and pharmacology research.

Hexavalent Chromium

Chromium may exist in nine valence states; however, only two are generally relevant for environmental and occupational risk assessment: trivalent chromium [Cr(III)] and hexavalent chromium [Cr(VI)]. It is important to speciate the valences of chromium for health risk assessment as the valences have distinctively different properties that are important for characterizing toxicity and exposure [1]. While Cr(III) is an essential micronutrient with very low potential to cause toxicity, Cr(VI) is better absorbed into cells with far greater toxic potential, causing damage at the site of exposure, particularly the skin, gastrointestinal tract (GI), and respiratory system. Upon high level exposures, Cr(VI) may cause systemic effects in the kidney, liver, and anemia [2]. Cr(VI) is also recognized as a human carcinogen, causing lung cancer in workers exposed to high concentrations in certain industries. Reduction of Cr(VI) to Cr(III) is a detoxification mechanism when occurring extracellularly such as in fluids and tissues of the body, including saliva, gastric acid, the liver, and blood [3]. Cr(VI) has not been shown to cause cancer outside the respiratory tract in humans; however, a recent study has shown that very high exposures to Cr(VI) in drinking water can cause cancer in the oral cavity and small intestine of rats and mice, respectively [2].

Cr(III) is the thermodynamically stable form of chromium in most environmental media and the form that occurs naturally in soil. Cr(III) primarily occurs as relatively insoluble oxides or hydroxides at concentrations ranging from 1 to 2000 mg kg⁻¹ [4]. Cr(VI) is produced from chromite ore, which is rich in naturally occurring Cr(III), in the chromate chemical production industry. While very low concentrations of Cr(VI), typically less than 10 ppb, may occur naturally in soil and ground water [5], exposure to Cr(VI) primarily occurs in association with anthropogenic activity, such as in certain industries or from environmental pollution. Because Cr(III) is relatively insoluble at neutral pH, chromium in solution in filtered ground water and drinking water is frequently primarily in the hexavalent state [5, 6].

In addition to chromate production, workers in many industries, including wood treatment, leather tanning, refractory production, ferrochromium and stainless steel production, metal plating and anodizing, pigment production, and those that use chromium

in pigments, paints, and primers and those involving contact with wet cement, have exposure to chromium [7, 8]. The health effects of Cr(VI) are well recognized as a result of high concentration airborne and dermal exposures to Cr(VI) in certain industries [9]. Historical occupational exposures occurring in chromate production, pigment production, and chrome plating have been associated with an increased risk of lung cancer, and several quantitative risk assessments have been derived for lung cancer risk associated with inhalation exposure in the chromate production industry [8]. Other health effects that are recognized to be associated with occupational exposure to Cr(VI) include allergic contact dermatitis (ACD) from contact with wet cement, which contains Cr(VI); it is also highly alkaline and irritating to the skin. Also, historical exposures in some industries have been associated with mild to severe irritation of the upper respiratory tract resulting in tissue damage, which has at extreme exposures, caused nasal septum perforation [10].

Studies of populations with environmental exposures to chromium have mostly been negative [11–13]. While one study of Chinese villagers reported an increased risk of stomach cancer in association with drinking Cr(VI)-contaminated well water [14], there are significant limitations with the exposure and mortality data for this cohort rendering the conclusions questionable [15]. Although it is generally more difficult to study disease outcome in environmentally exposed populations, health risk assessment methods have been developed over the past 20 years to predict the potential hazards associated with Cr(VI) from low level environmental exposures and set cleanup goals and exposure limits for environmental media.

This article describes important health risk assessment principles for evaluation of Cr(VI), based on the current state of the science, and includes discussions of hazard identification, exposure assessment, and toxicity assessment wherein the quantitative dose–response relationships (*see Dose–Response Analysis*) are described. Approaches used to characterize the risk associated with environmental and occupational exposure and set exposure limits are quantitatively described.

Hazard Identification

The health effects associated with oral, dermal, and inhalation exposures that are used as the basis for risk

assessment are discussed here. Extensive discussions of the potential hazards associated with chromium have been provided in agency reviews [4, 8, 9, 16].

Oral

Oral exposure to Cr(III) has generally demonstrated very low bioavailability and toxicity [16]. Because low exposures (e.g., 1 mg l^{-1}) to Cr(VI) are thought to be reduced to Cr(III) in the stomach [17], Cr(VI) toxicity from ingestion exposure has not been reported, except at very high doses. However, at exposures that overwhelm these defenses, tissue damage in the GI, liver, and kidney occur. The most definitive studies of the potential for Cr(VI) to cause reproductive and developmental toxicity in rodents were negative [18, 19].

A recently completed study by the National Toxicology Program (NTP) found that exposures to Cr(VI) at high concentrations can result in an increase in oral cavity cancer in rats and small intestinal cancer in mice [2]. Interestingly, the effects were species specific, e.g., small intestinal tumors did not occur in rats and oral cavity tumors did not occur in mice. Further, increases in tumor occurrence were exclusive to the oral cavity and GI, even though very high levels of chromium circulated systemically in this study. The oral cavity tumors occurred at concentrations of Cr(VI) exceeding 60 mg l^{-1} , and the small intestinal tumors occurred at exposures that exceeded 20 mg l^{-1} . These concentrations of Cr(VI) are highly discolored, and it is not likely that humans would chronically consume Cr(VI) at these levels. Decreased water consumption and body weight were reported in the NTP study for the highest dose groups. These levels of Cr(VI) are also hundreds to thousands of times higher than current human to Cr(VI) in drinking water (Figure 1).

Dermal

Cr(VI) is also a dermal sensitizing agent and can cause ACD among individuals who are allergic to it. Cr(VI)-induced ACD is a Type IV cell-mediated allergic reaction [20]. It is manifested as eczematous erythema (redness), pruritus (itching), and the formation of vesicles and papules on the skin, accompanied by scaling. The reaction is of delayed onset and, depending on the severity, can continue for several weeks if left untreated. Cr(VI)-induced ACD

Figure 1 Comparison of Cr(VI) drinking water exposure concentrations in National Toxicology Program rat and mouse cancer bioassay with US total chromium maximum contaminant level (MCL) and 95th percentile drinking water concentrations in United States and California

has been observed in occupational settings, including chrome plating, chromite-ore processing, lithography, leather tanning, and work involving repeated dermal contact with wet cement [21–23]. Because leather is tanned with chromium chemicals, the primary source of nonoccupational dermatitis due to chromium is contact with leather products, such as in footwear and watchbands [24].

ACD is typically described in two phases: induction (or sensitization) and elicitation [25]. In the induction phase, the chemical penetrates into the skin and is taken up and processed by antigen-presenting cells, to activate an allergic response. In the second phase, called elicitation, reexposure to the same allergen activates the memory T cells to trigger an inflammatory response, which results in the clinical symptoms of ACD [25]. Elicitation of ACD is a threshold response in which single or repeated exposures to low doses of Cr(VI) may not produce an allergic response if the threshold dose is not reached [23]. It is generally believed that it takes a higher dose to induce sensitization than to elicit symptoms of ACD (i.e., the elicitation threshold is lower than the induction threshold) [26]. Therefore, dermal standards protective of elicitation of ACD are also protective of the induction of sensitization to Cr(VI).

Cr(VI)-induced ACD is not life threatening, and the effect is generally limited to the skin. The other

type of skin reaction that can occur in response to chemical exposure is irritant contact dermatitis. A cutaneous irritant causes direct damage to the skin without prior sensitization [20, 27]. By comparison, irritant dermatitis is nonimmunological, has a more rapid onset than ACD, and exhibits a more rapid recovery on discontinuation of exposure [27].

Although no survey of the US general population has been conducted to assess the prevalence of allergy to Cr(VI), the prevalence of Cr(VI) allergy among clinical populations – individuals visiting the dermatologist for symptoms of contact allergy – suggests that only a very small fraction of the general population is likely to be allergic to Cr(VI) [23, 28, 29]. Of the more than 17 000 individuals patch tested by physician members of the North American Allergic Contact Dermatitis Group (NACDG), the percent with positive reactions to Cr(VI) has been low: 2.0% in 1994–1996, 2.8% in 1996–1998, 5.8% in 1998–2000, and 4.3% 2000–2002, and of these only approximately 50–70% of the positive responses were considered relevant by the treating physicians [30]. The prevalence rate in the general population, as compared to these data for clinical population patch tested for Cr(VI) allergy as reported in Pratt *et al.* [30], is obviously expected to be much lower [29].

Dermal contact with Cr(VI) has not been shown to cause cancer in animals or humans.

Inhalation

Respiratory tract effects are the most sensitive endpoint for inhalation exposure to Cr(VI), and most importantly, workers exposed to high concentrations of Cr(VI) have experienced an increased risk of respiratory tract cancer, primarily lung cancer [8, 31]. Cr(VI) has also been shown to cause lung cancer in animals upon inhalation and intrabronchial instillation [32, 33]. Cancer of the respiratory system is typically associated with significant tissue irritation and inflammation. Cr(III) is generally not regarded as an inhalation carcinogen and studies of workers exposed to chromium primarily in the trivalent state (e.g., ferrochrome production, tanning) have not demonstrated an increased risk of cancer [34, 35]. Inhalation of Cr(III) at extremely high concentrations ($>4 \text{ mg m}^{-3}$) has caused inflammation effects in the respiratory tract in rats [32, 36, 37].

While inhalation exposure to Cr(VI) has been associated with lung cancer among workers of certain industries, cancer outside the respiratory tract

has typically not been reported [15]. In a recent meta-analysis of chromium exposure and risk of cancer of kidney, stomach, prostate, central nervous system, leukemia, Hodgkin's disease, and lymphohematopoietic cancers, the only significant positive association was found for lung cancer [38]. This is thought to be due to the reduction of Cr(VI) to Cr(III) in the blood and liver following inhalation exposure [3]. Cr(VI) is a respiratory carcinogen that causes cancer at the site of exposure, but is detoxified through reduction in the red blood cells (RBCs) and liver, so that tumors are not observed at locations distant from the site of exposure [3, 15]. Physical and chemical properties of Cr(VI) are important in understanding carcinogenicity. Forms of Cr(VI) that are sparingly soluble – such as calcium and zinc chromate, have a longer biological half-life in the lung and greater carcinogenic potency than forms that are freely soluble – such as chromic acid and sodium dichromate [33, 39]. Also, particle size is important. For example, Cr(VI) in the chromate production industry involves exposure to ultrafine particles (particulate matter (PM) of $<2.5 \mu\text{m}$), and many studies have found an increased risk of lung cancer in this industry [31]. However, among aerospace workers exposed to particles of Cr(VI) in painting and priming, exposures are to much larger particles ($10\text{--}20 \mu\text{m}$), and no study of aerospace workers has reported an increased lung cancer risk [40, 41].

Exposure Assessment

Important considerations in the exposure assessment for chromium are (a) speciating valence state in environmental media, (b) environmental conditions such as pH and oxidation–reduction potential (ORP) dictated valence and bioavailability, (c) Cr(VI) is unstable in the presence of reducing agents, such as organic matter, reduced iron and sulfides, and is converted to Cr(III) – this reaction occurs more rapidly in acidic conditions, and (d) natural sources of both Cr(III) and Cr(VI) should be differentiated from anthropogenic sources. Exposure assessment in air, soil and sediment, and water are discussed in greater detail below.

Air

Because Cr(VI) is recognized as an inhalation carcinogen and Cr(III) is not, it is very important

to speciate Cr(VI) from total chromium in airborne samples for risk assessment. It is also important to characterize the particle size to understand the respirable fraction that can be inhaled and distributed to the lung.

Cr(VI), at ambient conditions, exists as a particulate, not as a vapor. Air sampling and analysis methods for total and hexavalent chromium in occupational and environmental settings have been developed by National Institute for Occupational Safety and Health (e.g., NIOSH Method 7604), and US Environmental Protection Agency (EPA) (e.g., Method 68-D-00-246). As airborne concentrations of Cr(VI) in environmental settings are generally less than 1 ng m^{-3} , it is important to use a method with a sufficiently low limit of detection, generally achieved through use of an ion exchange separation column. For example, concentrations of Cr(VI) in southern California range from 0.03 to 23 ng m^{-3} , with annual mean values by monitoring station that range from 0.04 to 1.24 ng m^{-3} [42].

Soil and Sediment

Because there are important differences in the toxicity of Cr(VI) and Cr(III), it is important to speciate Cr(VI) from total chromium in soils and other solid media, including sediment. Further, because Cr(III) is naturally occurring in soil and sediments at concentrations that typically range between 20 and 200 mg kg^{-1} , it is important to be able to differentiate naturally occurring Cr(III) from Cr(VI), which is not expected to be naturally occurring in soil or sediment, for risk assessment. In some cases the level of concern for Cr(VI) may be below naturally occurring levels of Cr(III). Further, it is important to consider that Cr(VI) may pose an inhalation cancer risk in soil because inhalation exposure might occur by suspension of Cr(VI)-bound to soil through wind erosion of vehicle traffic on unpaved soils. Methods for risk assessment of Cr(VI) in suspended soil have been described in Scott and Proctor [43] and EPA [44].

Cr(VI) is typically not present in sediments owing to the abundance of reducing agents; thus total chromium in sediments is generally not a health or environmental concern. Berry *et al.* [45] recently developed the "Cr hypothesis" for evaluating chromium in sediments. The hypothesis states that chromium is of low toxicity in sediments with measurable acid volatile sulfides (AVS) because the conditions are reducing and chromium exists as Cr(III)

which has very low bioavailability and toxicity. This hypothesis has been demonstrated to be correct in several environmental settings [46, 47].

Similar to sediments, the bioavailability or bioaccessibility of chromium in soils is also an important consideration in risk assessment [1]. Chromium that cannot be removed from the soil matrix by biological media is not available for absorption into cells and does not pose a health hazard. Although Cr(VI) is generally soluble in soil, there is also likely to be a fraction that is insoluble and not bioavailable. By comparison, Cr(III) in the oxide or hydroxide form is relatively insoluble, and this characteristic renders most Cr(III) in the environment of negligible bioavailability and toxicity [48]. Two exceptions to this rule involve Cr(III) in sewage sludge and tannery waste [48]. Forms of Cr(III) in these waste streams may be bound to organic molecules or in solution in acidic environments such that their potential bioavailability is much greater. While soluble forms of Cr(III) in soil can be oxidized to Cr(VI) in the presence of manganese oxide, at the same time (a) the reaction is cyclical (i.e., Cr(VI) oxidized from Cr(III) is reduced by reducing agents present in the environment); (b) it is facilitated at lower pH; (c) only soluble forms of Cr(III) may be oxidized to Cr(VI); and (d) only a low percentage, less than 5% of soluble Cr(III), is oxidized [48]. The conditions dictating speciation in soil and sediment are presented in Figure 2. Bioavailability of Cr(VI) in soils and sediments is most appropriately evaluated on a site-specific basis.

Water

In neutral conditions, Cr(III) is typically insoluble and falls out of water as a particulate. Cr(VI) is soluble in neutral and alkaline conditions, and predominates in filtered water. California Department of Health Services (CDHS) [6] has evaluated the levels of Cr(VI) in drinking water from more than 7000 drinking water sources in California and found low levels of Cr(VI), typically ranging from 1 to 10 ppb , in approximately one-third. Most Cr(VI) in CA drinking water is believed to be from natural sources [6]. Similarly, other researchers have found naturally occurring Cr(VI) in groundwater [5, 49]. Levels of naturally occurring Cr(VI) are typically very low ($<50 \text{ } \mu\text{g l}^{-1}$). An extensive data set of potential drinking water data developed by the United

* Rate and occurrence of oxidation/reduction reactions are pH dependent

Figure 2 Factors affecting Cr(VI) stability in environmental media

States Geological Survey (USGS), EPA, and the State of Texas of Cr(VI) and total chromium in ambient groundwater wells includes approximately 25 600 samples from locations across the United States. Cr(VI) was not detected in 48% of the samples in which it was analyzed. The geometric mean and 95th percentile Cr(VI) concentrations were 1.5 and 16 $\mu g\ l^{-1}$, respectively, and those for total chromium were 5.8 and 50 $\mu g\ l^{-1}$, respectively [50].

The current drinking water standard, maximum contaminant level (MCL), in the United States is for total chromium, but is designed to be protective of total chromium as Cr(VI). The MCL is protective of noncancer health effects as quantified using the Cr(VI) reference dose (RfD), which is discussed in the Toxicity Assessment section of this chapter. The MCL was originally set at 50 $\mu g\ l^{-1}$ in the 1970s, then revised to 100 $\mu g\ l^{-1}$ in 1991 [51]. The standard is for total chromium rather than for Cr(VI) because the laboratory analysis for total chromium is simpler, less expensive to conduct and, until improvements take place in the analytical chemistry, achieves a lower limit of detection.

Toxicity Assessment

The methods used to quantify the dose–response relationship for chromium are valence specific and different for cancer and noncancer health effects. Noncancer health effects are quantified using a RfD or RfC (reference concentration), which are typically calculated by dividing a no-observed-adverse-effect level (NOAEL) by uncertainty factors to account for limitations in the NOAEL for describing a threshold dose for sensitive humans. For carcinogenic effects, the relationship between dose and response is typically described using a unit risk factor or cancer slope factor, which describes the relationship between the increased risk or rate of cancer with increasing dose. For inhalation cancer risk assessment of Cr(VI), it is typically assumed that the dose–response observed at the high dose range can be extrapolated to the low dose range with the assumption of linearity and no threshold [16, 52, 53]. No biologically based dose–response model for Cr(VI) currently exists.

Noncancer Toxicity Assessment

Oral. The EPA RfDs for both Cr(III) and Cr(VI) are based on NOAELs observed in rats. The Cr(VI) RfD is based on a drinking water study in which no effects were observed at doses up to $2.5 \text{ mg kg}^{-1} \text{ day}^{-1}$ for 1 year, the highest dose administered [54]. To the NOAEL, a 300-fold uncertainty factor was applied to account for variability between species, sensitive subpopulations, the less than lifetime exposures in the principle study, and uncertainties regarding the reproductive toxicity of Cr(VI) to result in an RfD of $0.003 \text{ mg kg}^{-1} \text{ day}^{-1}$. The EPA RfD for Cr(VI) may be revised in the future based on the results of the 1996, 1997, and 2007 NTP studies [2, 18, 19]. While the NTP studies demonstrated that the uncertainty factor used to account for inadequate information regarding reproductive toxicity is not necessary, the results suggest a much lower effect level in mice as compared to rats (lowest-observed-adverse-effect level (LOAEL) of $0.4 \text{ mg kg}^{-1} \text{ day}^{-1}$ in mice). The NTP study results for rats are consistent with the current RfD, but if the findings in the mouse are deemed of greater relevance for human exposures, the RfD could be decreased accordingly.

Inhalation. Inhalation RfCs are used for noncancer toxicity assessment in a manner similar to RfDs. RfCs are the concentration of a chemical in air, which can be inhaled continuously over the course of a lifetime, and not pose deleterious effects, even among sensitive human subpopulations. EPA has not set an RfC for Cr(III) because there is inadequate data to do so, and the information that does exist suggests that Cr(III) is of limited bioavailability and toxicity [16]. However, for Cr(VI), RfCs have been developed for different forms of Cr(VI), chromic acid mists and Cr(VI) soluble salts/particulates. Separate values have developed because of the recognized differences in toxicity of certain Cr(VI) chemicals. Because of its highly irritating properties, an RfC of 8 ng m^{-3} has been set for chromic acid mists. Chromic acid mists might occur in proximity to a chrome-plating facility, but the environmental half-life is relatively short in this chemical form. For most environmental exposures, Cr(VI) is expected to be in the form of a chromate or dichromate salt [55]. The Cr(VI) RfC for soluble salts and particulates is 100 ng m^{-3} [16]. This RfC is based on a benchmark dose for pulmonary

Figure 3 Benchmark dose analysis used to develop the Cr(VI) reference concentration for particulates

inflammation in rats and uses a 300-fold uncertainty factor (Figure 3).

Cancer Risk Assessment

The cancer risk assessment for chromium focuses on the potential cancer risks associated with inhalation exposure to Cr(VI). Until the 2007 NTP rodent study, the weight of evidence indicated that Cr(VI) did not poses a cancer risk from ingestion exposure, and Cr(III) has not been considered carcinogenic *via* any route of exposure [15].

Oral Cancer Risk Assessment. While no quantitative cancer risk assessment for oral exposures to Cr(VI) have been developed to date, there are several important considerations when using the NTP rat oral cavity cancer and mouse small intestinal cancer data for human risk assessment.

First, ingested Cr(VI) is reduced to the trivalent state in the stomach [3, 17, 56]. This is a detoxification process, and it is reasonable to expect that it may be overwhelmed at high doses. The reduction capacity of the mouse stomach may be considerably less than that of the rat and that of a human, potentially explaining the occurrence of small intestine tumors in mice, but not in rats. The tissue data collected from the NTP study suggests that much higher

levels of Cr(VI) were passed from the stomach of the mouse to the small intestine, as compared to that of the rat, because much higher levels of Cr were observed in the mouse liver (Figure 4). Humans are expected to have even greater capacity to reduce Cr(VI) to Cr(III) in the stomach because of the much lower pH of the human stomach (fasting pH of ~ 1.5 – 2) as compared to a mouse or rat (glandular stomach pH of ~ 3) [57]. As a result, the dose necessary to induce tumors of the small intestine of a mouse may be far less than that which could induce tumors in humans and a physiologically based pharmacokinetic (PBPK) model should be used for interspecies extrapolations.

Second, many NTP studies for other chemicals have found that rats are more sensitive to oral cavity tumors than mice, and the rat oral cavity tumors were found in absence of non-neoplastic lesions that are suggestive of chronic tissue damage [2]. For this reason, it may be presumed that the mode of action (MOA) for oral cavity cancers is more complicated than Cr(VI) causing tumors from site-of-contact mutagenic activity or because of chronic hyperplasia. More research is needed to better characterize the MOA in rats, and it is possible that the observations in rats are species specific or only occur at extraordinarily high exposures.

Finally, it is important to consider that the doses to which the NTP rodents were chronically exposed far exceeds the levels of Cr(VI) to which human could be exposed to in drinking water (Figure 1). It is probable that drinking water exposures at the current exposure limit ($100 \mu\text{g l}^{-1}$ of total chromium) can be detoxified through reduction to Cr(III) before posing an oral cancer hazard.

Inhalation Cancer Risk Assessment. The dose–response for increased cancer risk associated with inhalation exposure to Cr(VI) has been quantitatively evaluated in several studies [8, 52, 58]. Because several epidemiological studies present increased lung cancer risk with increasing exposure, animal studies have not typically been used to quantify dose–response. Dose–response is quantified using a unit risk factor that is the increased risk associated with continuous exposure to $1 \mu\text{g m}^{-3}$ of Cr(VI) over an exposure period.

The unit risk factors calculated for occupational and environmental populations demonstrate general consistency between studies. For continuous environmental exposures (24 h day^{-1} for a lifetime) EPA calculated a unit risk factor of $0.0117 \mu\text{g}^{-1} \text{ m}^{-3}$ using the Mancuso [59] study, and using updated

Figure 4 Mean chromium concentrations in liver of NTP female mice and male rats by dose group

approaches, Crump *et al.* [52] calculated an environmental unit risk value of $0.00978 \mu\text{g}^{-1} \text{m}^{-3}$ using the epidemiology data of Luippold *et al.* [60]. Crump and colleagues also calculated an occupational unit risk value (for exposure 8 h day^{-1} for 45 years) of $0.00205 \mu\text{g}^{-1} \text{m}^{-3}$, and Park *et al.* [58] calculated a corresponding value of $0.0049 \mu\text{g}^{-1} \text{m}^{-3}$, and were able to quantitatively account for the risk associated with smoking in the cohort. While it is a distinct advantage to be able to quantify risk using human data and to have multiple data sets from which to conduct the quantitative evaluation, the limitations of these estimates are that they are all based on workers exposed in a single industry, chromate production, and are all based on high concentration exposures that occurred over a relatively short duration (e.g., few months to few years) extrapolated to low level exposures on the basis of cumulative dose. Finally, it is important to consider that these cohorts all had a very high prevalence of smoking.

Allergic Contact Dermatitis. The dose–response relationship for ACD is characterized using the 10% minimum elicitation threshold ($\text{MET}_{10\%}$) for Cr(VI). A recent study by Proctor *et al.* [61] developed a $\text{MET}_{10\%}$ based on a repeated open application test (ROAT) for a population of individuals who were previously known to be allergic to Cr(VI). The study was performed to provide improved data for assessing the potential risk posed by Cr(VI) in environmental exposure situations (e.g., dermal contact with Cr(VI)-contaminated soil). The $\text{MET}_{10\%}$ from this study can be used to develop an RfD for dermal contact (skin-RfD, or s-RfD) for risk assessment of Cr(VI) in treated wood or in environmental media. Because the $\text{MET}_{10\%}$ is dependent on the sensitivity of the study population, Proctor *et al.* weighted $\text{MET}_{10\%}$ value to the patch-test reaction grades of the North American Allergic Contact Dermatitis Group. The resulting $\text{MET}_{10\%}$ values are provided in Table 1. Proctor *et al.* [61] also provided $\text{MET}_{10\%}$ values for two scenarios: (a) scenario 1 included only responses deemed to be allergic in nature by the principal investigator and (b) scenario 2 is based on all responses including allergic and those deemed to be irritant in nature.

No Uncertainty Factor (UF) factors are needed to convert the $\text{MET}_{10\%}$ values to s-RfDs because the tests were performed on sensitive humans, and ACD is an acute affect. For application of the s-RfD to the

Table 1 $\text{MET}_{10\%}$ calculated for scenarios 1 and 2 from the Proctor *et al.* [61] study and the patch-test-normalized populations for repeated open application test challenges to potassium dichromate^(a)

Population	Scenario ^(b)	Modeled $\text{MET}_{10\%}$ (ng of Cr(VI)/cm ²)
Proctor <i>et al.</i> study population	1	118
Patch-test-normalized population	1	364
Proctor <i>et al.</i> study population	2	86.6
Patch-test-normalized population	2	269

^(a) Reproduced from [61]. US Environmental Protection Agency, 2006

^(b) Scenario 1 includes allergic responses only; Scenario 2 includes all allergic and irritant responses

general population, the $\text{MET}_{10\%}$ value for the patch-test-normalized value is more appropriate. Thus, the s-RfD for the general population of Cr(VI) sensitized individuals is $269 \text{ ng of Cr(VI)/cm}^2$ for all responses (irritant and allergic) and $364 \text{ ng of Cr(VI)/cm}^2$ for allergy. Interestingly, the study population $\text{MET}_{10\%}$ of $118 \text{ ng of Cr(VI)/cm}^2$ from the Proctor *et al.* ROAT study is $\sim 30\%$ higher than that developed by Nethercott *et al.* of $89 \text{ ng of Cr(VI)/cm}^2$ using occlusive patch testing [28, 61]. The data necessary to weight the results by patch-test grade was not provided in the Nethercott *et al.* study; thus these data could not be normalized by patch-test grade.

Risk Characterization

Risk characterization is performed by combining the hazard identification, toxicity assessment, and exposure assessment to yield quantitative risk estimates and health-based guidelines for environmental media (*see Environmental Hazard; Environmental Health Risk*).

Cr(VI) Guidelines for Soil, Treated Wood, and other Surfaces Based on ACD

On the basis of the approach described in Nethercott *et al.* [28] and the patch-test-normalized $\text{MET}_{10\%}$ developed in Proctor *et al.* [61] ROAT study (364 ng cm^{-2}), the calculated soil standard that is

protective of ACD from contact with Cr(VI) in soil is 1820 mg kg^{-1} . While this value exceeds EPA's soil screening levels (SSLs) that are protective of Cr(VI) for soil ingestion and inhalation at residential sites [44], it is lower than that for soil ingestion for commercial and industrial sites and provides useful information for the risk assessment of Cr(VI) from short-term (acute) exposures to soil for other scenarios, such as soil contact for a construction worker. These data may also be used to assess the potential dermal exposures to Cr(VI) on surfaces such as building walls or equipment.

Cancer Risks Associated with Cr(VI) in Air

The theoretical excess cancer risk from inhalation exposure is quantified using measured or model predicted levels of Cr(VI) in air and cancer slope or unit risk factors for occupational and continuous lifetime exposures [52]. Although derived from human data, these factors are recognized to have several uncertainties and generally thought to overestimate risk at low levels of exposure. This occurs because the slope factors are based on high concentration exposures that occur over a relatively short duration which are used as a cumulative dose (e.g., 1 year of exposure to $100 \mu\text{g m}^{-3}$ is assumed to be equal to 40 years of exposure at $2.5 \mu\text{g m}^{-3}$). Using Occupational Safety and Health Administration (OSHA's) risk assessment, the theoretical excess lung cancer risk at the new limit of $5 \mu\text{g m}^{-3}$ for a 45-year occupational lifetime is 10–45 per 1000 [8]. Using the EPA [16] and Crump *et al.* [52] environmental risk assessments, the theoretical excess cancer risk associated with lifetime exposure to Cr(VI) at 1 ng m^{-3} – the approximate upper bound of background concentration of Cr(VI) in ambient air in urban areas, is 1 in 100 000.

Health-Based Soil Guidelines for Protection of Human Health and Wildlife

The environmental and human health risks posed by Cr(VI) in soil are characterized from many potential exposures including leaching to groundwater, non-cancer hazards due to dermal contact and incidental ingestion, and the potential cancer risk associated with inhalation of particulates suspended from vehicle traffic and wind erosion. Health-protective guidelines for Cr(VI) for industrial/commercial properties,

which support significant vehicle traffic, and construction scenarios involving significant dirt moving activities, can be more conservative (e.g., lower) than those protective of residential land use owing to the potential cancer risk associated with inhalation of suspended particulates [62]. Soil standards for residential land use protective of ingestion exposure among children are typically around 230 mg kg^{-1} [44], whereas the level protective of workers at sites with vehicle traffic can be in the range of $20\text{--}30 \text{ mg kg}^{-1}$ [44, 63]. Levels of Cr(VI) protective of drinking water sources are dependent on site-specific conditions, with default values that range from 2 to 20 mg kg^{-1} [44]. For all scenarios, particularly for leaching to groundwater and soil suspension owing to vehicle traffic, risk assessment and determination of cleanup levels should be performed on a site-specific basis, considering actual site conditions.

The US EPA has developed risk-based ecological soil screening levels (Eco-SSLs) for Cr(VI) and Cr(III). The Eco-SSLs are defined as chemical concentrations that are protective of ecological receptors that commonly come into contact with soil, or ingest biota that live in, or on, soil. If sufficient toxicological data are available for a chemical, Eco-SSLs are derived separately for four diverse groups of ecological receptors: plants, soil, invertebrates, and wildlife (i.e., birds and mammals). Sufficient toxicological information on chromium was available to derive Eco-SSLs only for wildlife receptors. For avian receptors, sufficient information was available to develop an Eco-SSL only for Cr(III), whereas for mammalian receptors sufficient information was available to develop Eco-SSLs for both Cr(III) and Cr(VI). The Eco-SSLs for Cr(VI) for mammalian receptors is 81 mg kg^{-1} [64].

Drinking Water Standard

The US federal drinking water standard of $100 \mu\text{g l}^{-1}$ (ppb) is for total chromium but designed to be protective of Cr(VI) for noncancer effects [51]. As the MOA and cancer risk assessment of Cr(VI) is developed from the recent NTP rodent bioassay, it is expected that these standards may be revised in the future and that separate standard for Cr(VI) and Cr(III) will be developed. Research to evaluate the MOA for these tumors, interspecies variability and extrapolation from rodents to humans, and low dose extrapolation of the dose–response relationship will

be necessary for use of the NTP data for human risk assessment of ingested Cr(VI).

History and Examples of Environmental Justice

Environmental Justice Defined and its Relationship to Risk

Definition of Environmental Justice

Environmental justice refers to the spatial distribution of environmental risks, and costs and benefits across different population groups associated with siting, development, regulatory, and policy decisions that involve both the public and private sectors. Population groups included in environmental justice analyses are typically categorized by factors such as race, ethnicity, income and age. The United States Environmental Protection Agency (USEPA) defines environmental justice as follows [1]:

“Environmental Justice is the fair treatment and meaningful involvement of all people regardless of race, color, national origin, culture, education, or income with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies. Fair Treatment means that no group of people, including racial, ethnic, or socioeconomic groups, should bear a disproportionate share of the negative environmental consequences resulting from industrial, municipal, and commercial operations or the execution of federal, state, local, and tribal environmental programs and policies. Meaningful Involvement means that: (1) potentially affected community residents have an appropriate opportunity to participate in decisions about a proposed activity that will affect their environment and/or health; (2) the public’s contribution can influence the regulatory agency’s decision; (3) the concerns of all participants involved will be considered in the decision-making process; and (4) the decision-makers seek out and facilitate the involvement of those potentially affected.”

Relationship to Risk Assessment and Risk Management: Some Examples

When risk-assessment and risk-management strategies and techniques were first developed, population as the target of potential exposures was viewed in the aggregate; that is, population was usually not

subdivided into population sectors. The individual was usually considered the unit of exposure. As the civil rights and environmental movements emerged, justice issues by population sector emerged. Some examples are noteworthy. First, in the *environmental health risk assessment* (see **Environmental Health Risk**) area, the exposure component of risk assessment methodologies involves estimates of the amount of a contaminant that is absorbed. Fish is consumed in different ways and in different quantities by population sector. Some low-income populations, for example, consume fish from waters that are more contaminated than others. Some populations consume the entire fish rather than just small portions of it. Finally, fish constitutes a greater proportion of the diets of some populations than others. All of these situations imply the need to adapt exposure values by population sector. Secondly, asthma is now considered to be on the rise. Hospitalizations due to asthma tend to be concentrated in low-income and minority areas, for example, in New York City [2]. This suggests a need to divide risk assessments based on air quality and inhalation according to population sector (see **Air Pollution Risk**).

The History and Origin of Environmental Justice

The Evolution of the US Experience

Environmental justice is a lens through which to view risks to human life, health, and well-being. It has evolved in the United States over decades and in many contexts. The common theme, as defined above, is the existence of disparities based on social and economic characteristics of individuals and groups. Social and economic characteristics of communities as a foundation for portraying disparities originally emphasized race and class. These categories have been expanded to include many other often overlapping characteristics considered to potentially reflect human vulnerabilities. For example, susceptibility to added burdens of pollution are potentially associated with ethnicity, since certain lifestyles are associated with exposure to different levels of pollution; certain potentially vulnerable age groups, in particular, the very old and the very young; various life stages, such as pregnancy; and health status – those with disabilities or disease. Disparities pertain broadly to exposure to adverse conditions and

access to resources to reduce these exposures and their adverse effects.

Several concepts have emerged to characterize these concerns, namely: equity, justice, and racism. Environmental equity and environmental justice are distinctly different concepts: equity being a more neutral term referring to distribution of assets or opportunities, whereas justice is normative encompassing the fairness of a distribution or opportunities [3, p. 633]. Racism further encompasses a deliberate attempt at shifting the distribution of burden and discrimination.

The origins of environmental equity, justice, and racism in the United States are generally attributed to the civil rights movement of the mid-twentieth century ([4, p. 650], and codified in Title VI of the Civil Rights Act of 1964 (Public Law 88–352, Title VI, Sec. 601, July 2, 1964, 78 Stat. 252)) that required that “No person in the United States shall, on the ground of race, color, or national origin, be excluded from participation in, be denied the benefits of, or be subjected to discrimination under any program or activity receiving Federal financial assistance.” During the late 1960s and the decade following, most of the major environmental laws were passed, many involving substantial federal funding, thus potentially invoking the requirements of Title VI. Implementing this order in the context of environmental law occurred initially with respect to abandoned hazardous waste disposal sites. In 1980, the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA, known as the *Superfund Act*) was passed to regulate these sites. The United States General Accounting Office (US GAO, now called the *US Government Accountability Office*) identified one of the early cases of waste siting in a predominantly minority community in North Carolina [3, 5]. Following that, during the 1980s, waste sites were identified in communities of color and low-income communities throughout the country. Case studies moved to the realm of statistical analysis that captured environmental justice as a more widespread phenomenon [4, 6]. In 1987, the United Church of Christ published the report of a study of the racial and socioeconomic characteristics of the communities in which hazardous waste sites were located [7], published in a more extensive form a few years later [8]. In spite of the national attention drawn to this issue and the increasing sophistication of the methods of analysis, early environmental

justice cases involving waste sites were not won by environmental justice advocates. For example, three landfill cases were brought and lost by environmental justice supporters in the late 1980s and early 1990s – *Bean v Southwestern Waste Management Corp.*, *East Bibb Twiggs Neighborhood Association v Macon-Bibb County Planning & Zoning Commission*, and *R.I.S.E., Inc. v Kay*. The cases were brought on the basis of disproportionate shares of minorities in some of the areas surrounding landfills, but the cases were lost due in part to the lack of specific benchmarks to interpret those shares and the focus of the courts on intentionality or discrimination, which they felt were not supported [3, 4].

Attention to environmental justice spread from a focus on waste disposal sites (both active and inactive or abandoned) to other forms of pollution, for example, *air pollution* (see **Air Pollution Risk**) [9]. Two decades after the formal emergence of the environmental movement in the United States, the president signed an executive order, E.O. 12989 in 1994, which underscored procedures to incorporate environmental justice throughout federal actions [10].

Paralleling environmental justice issues in connection with waste and other environmental exposures was the emergence of injustices in the area of infrastructure, many of which were connected with environmental contamination. The adverse environmental aspects of transportation, water, and energy have emerged as key justice issues [11]. In 2001, transportation accounted for 82% of carbon monoxide emissions, 56% of nitrogen oxide emissions, and 42% of volatile organic compounds; energy accounted for 86% of sulfur dioxide emissions and 39% of nitrogen oxides from fuel combustion [12: 580]. These pollutants are the key regulated air pollutants under the Clean Air Act. Transportation poses multifaceted justice issues, for example, in connection with lack of access to public transit forcing reliance of lower income people on older automobiles that expose them to higher emissions. A key justice issue related to transportation pertains to the proximity of lower income groups to roadways and traffic increasing their exposure to transportation-related air pollutants and noise [13]. Risk-related quantitative approaches have been applied to transportation justice issues [14]. In the area of energy, similarly, the poor, racial and ethnic minorities may seek lower cost housing near power plants. The siting of natural gas fired turbines in low-income New York City neighborhoods, in

2001, to alleviate a summer power shortage was very controversial in that the decision bypassed normal environmental reviews [15]. Water rights and water quality issues have been a continual subject of environmental justice both nationally and internationally [16] and the latest USEPA strategic plan also prioritizes this area [17]. Injustice issues have arisen in connection with other areas of infrastructure, not directly related to environmental conditions, such as access to computers and the internet.

Linkages between environmental conditions and injustices were largely drawn on the basis of proximity. Though proximity is still commonly used, in the late 1990s and early 2000s, more direct and sophisticated measures of environmental health risk emerged through the availability of risk models. The USEPA working group in its 1992 report underscored the integration of environmental justice into risk-based approaches for environmental protection [18]. Models continued to be developed that often included a geographic component through the use of geographic information systems (GIS) [19, p. 246]. In that way, these models not only provided direct measures of risk, but also enabled proximity measures to be linked to them thus strengthening their use as a surrogate measure for environmental risk.

The 1990s saw some of the most devastating and catastrophic natural hazards ever experienced in the United States. The World Bank reported that 3.4 billion people worldwide were exposed to at least one natural hazard, and that the likelihood of experiencing some of the greatest losses and highest costs was higher in poorer countries [20]. Once again there were indications that exposure to and effects of these hazards were in many cases felt disproportionately by certain sectors of society. Studies of Hurricane Andrew, one of the most devastating and costly weather-related catastrophes, identified low-income and minority communities as those that were not able to seek shelter or recover [21]. The Gulf Coast hurricanes of August–September 2005 dealt a final blow. Low-income groups and communities of color experienced the worst of the devastation, since much of their housing was in low-lying areas. These communities experienced the largest burden in terms of the ability to escape and then recover and rebuild. Environmental concerns among racial minorities in the Gulf Coast area were recognized almost 10 years prior to the flooding [22]. Environmental justice continues to evolve as environmental issues have

changed. For example, it has now emerged as a dimension of sustainability [23, 24]. Five principles of equity that can be related to environmental justice are defined in the field of sustainable development: intergenerational equity, intragenerational equity, geographical equity, procedural equity, and interspecies equity [25].

International Issues in Environmental Justice

Environmental justice and fairness issues are also prominent in discussions about developing countries and global issues. Two areas where environmental justice is often invoked in international policy discussions are global climate change and the transboundary movement of toxic and hazardous substances. In the case of global climate change, the discussions center around past greenhouse gas emissions as countries expand their economies, and about projected emissions and their expected impact. This divide between developed and developing countries was prominent in discussions about the *Kyoto Protocol to the United Nations Framework Convention on Climate Change* [26]. The United States argued that it would not ratify binding emission reduction targets if developing countries such as China and India did not commit to reductions as well. Developing countries argued that it would be unfair for developed countries to have benefited from emitting large amounts of greenhouse gases as they developed and to now impose restrictions on poor countries that are attempting to raise the standard of living of their citizens [27, 28]. Measures of greenhouse gas emissions, such as carbon dioxide (CO₂), methane (CH₄), and nitrous oxides (NO_x) are presented as total emissions, emissions per capita, and emissions per unit of gross domestic product (GDP).

The other area where environmental justice plays a prominent role is in the regulation of transboundary movements of hazardous and toxic substances (*see Fate and Transport Models*). As developed countries implemented stricter environmental regulations since the 1960s, the cost of disposal of toxic and hazardous wastes increased substantially. A growing number of cases where these wastes ended up being dumped in developing countries without adequate disposal capabilities resulted in the growing concern about fairness and environmental justice (*see Hazardous Waste Site(s)*). Such cases are still being reported. In 2006, a large toxic sludge that originated in Europe was dumped untreated near a poor

neighborhood in Abidjan, Ivory Coast. The sludge was blamed for at least eight deaths and hundreds of cases of nausea, headaches, skin sores, nose bleeds, and stomach aches [29]. Concern about cases of toxic and hazardous waste dumping on developing countries with inadequate institutions and facilities to accommodate such wastes prompted members of the United Nations to ratify the Basel Convention, which was adopted in 1989. The main goals of the Basel Convention are to minimize the generation of hazardous waste, to safely dispose of these wastes as close as possible to their origin, and to regulate the transboundary movement of these wastes [30]. An additional concern is the international trade in e-waste, which refers to the disposal and the international trade of used computers and other electronic equipment. These products which are disposed of in developed countries often make their way to poor countries in Asia where they are taken apart and their constituent parts and materials are separated and reused. These activities take place under conditions that are often considered harmful and expose workers to high environmental risks [31].

Environmental justice and the distribution of environmental hazards are not limited to domestic discussions in developed countries. In the context of developing countries, lack of access to basic infrastructure services, such as potable water, wastewater disposal and treatment, and solid waste collection by underprivileged groups often leads to large human health burdens for these populations [32].

Methodologies to Discern the Evidence

A recent literature review of environmental justice studies concludes that people of color and lower socioeconomic status (SES) are exposed to higher levels of environmental risks according to outcome measures, such as proximity to hazardous waste facilities, exposures to air, noise, and water pollution, quality of housing and residential crowding, quality of schools and conditions of the work environment [33]. A well-documented example is lead levels in blood. Several studies have shown that children of minority communities and low-income groups have significantly higher levels of lead in the blood relative to the overall population [34]. An assessment of the environmental justice literature based on a meta-analysis of 49 studies concludes that there is strong

evidence of environmental inequities based on race but little evidence of environmental inequities based on economic class [19]. This section discusses some of the techniques used to assess environmental justice issues and the research challenges associated with this field of inquiry.

Environmental justice analyses have used a number of analytical tools including computer modeling, statistical modeling, and GIS to gain a better understanding of differential environmental risks to different populations. In the case of proximity analyses to sources of environmental risks, such as incinerators, waste disposal facilities, highways, and others, census data can be used to describe the neighborhood or community surrounding the source of risk. Among the socioeconomic characteristics included in such analyses in the United States are percentages of African-Americans, Hispanics, native Americans, households and individuals living below the poverty line, elderly people, and others. In examining the potential effects of proximity to facilities associated with air pollution emissions, additional measures that characterize vulnerable populations may also be included, such as percentage of children under the age of 17 who have had an asthma attack. Instead of using a single measure, more recent studies increasingly use multiple indicators that may also include rate of unemployment, types of employment, education level, and housing market characteristics such as price of housing and percentage of owners and renters [35].

Defining the neighborhood or community around a facility often represents a challenge to researchers since defining a unit of analysis that allows for a comparison with other units further away from the source of environmental risks is not always easy. Spatial units around the source of environmental risk and the census units typically used to obtain the characteristics of the geographical units are often different from each other. Moreover, the spatial distribution and density of people living within a unit of analysis may vary within each unit and among units. An early review of the issues involved in spatial definitions for environmental justice analysis was provided by Zimmerman [3]. In the United States, units of analysis used to obtain information about the area around a source of environmental risk include census block groups [36, 37] census tracts [36], zip codes [8], cities and metropolitan areas [4], and states [19]. Defining the unit of analysis can have important

Figure 1 Point buffers around a waste transfer station in Bronx County, New York [Reproduced from [36]. © New York University, 2002.]

consequences, and changing the scale of the unit of analysis may change the results of an environmental justice analysis [19, 37, 38].

Pioneering environmental justice studies used statistical modeling to predict the location of a source of environmental risk based on the characteristics of a neighborhood. Evidence of environmental injustice was reported if a positive statistical association between the likelihood of finding such a facility increased as the percentage of minorities and poor people increased in a neighborhood [7, 39].

GIS have become one of the most important analytical tools for environmental justice studies. Spatial coincidence studies map sources of environmental hazards and look for clustering of these sources. GIS maps of these types may also include socioeconomic characteristics of the populations in the area to see if

any clustering occurs in areas with high percentages of minority or disadvantaged groups. Another method used in GIS analyses is to create buffers around a source of environmental risk. The shape of the buffer depends on the distribution of the pollutant discharges around a source of risk. A line buffer looks at the characteristics within a specified distance along a line. Applications of line buffers include looking at the characteristics of populations around rail lines, highways or truck routes. Point buffers use circles around a point source of environmental risk, such as a hazardous waste handling facility. Figure 1 illustrates the use of point buffers and shows four buffers around a waste transfer station in Bronx County, New York. The radii of the buffers shown are 1/4, 1/2, 3/4, and 1 mile [36]. GIS is then used to extract information from sources such as the US census to understand the

characteristics of the population living in the specified buffer. These characteristics can then be compared with other areas, such as randomly generated buffers of equal size in other parts of the city or larger units, such as the city or the county.

Using buffers such as the ones shown in Figure 1 presents some important challenges when using data sources such as a census. The units of analysis of a census, such as census block groups, census tracts, and zip codes do not usually match the geometry of a point buffer of a specified radius. GIS software is used to extract the information by including only those units that are within the buffer or by making some assumptions about the units that are only partially within the buffer. Three methods are typically used to decide what type of information should be used in the estimates of population characteristics within a buffer [36]. In the polygon intersection method any unit that falls within the buffer, even if only partially, is included for estimates of population characteristics. This method tends to overestimate the results if significant portions of a unit of census data fall outside the buffer. The polygon containment method includes only those units that fall completely within the buffer. This method tends to underestimate population characteristics if a significant number of the census units are only partially within the buffer and thus not included in the estimates. The aerial interpolation method includes all units that are totally or partially within the buffer. However, for those units that are only partially within the buffer this method estimates the population characteristics by making the assumption that the population is evenly distributed within the unit or by using an area weighted technique and apportioning that data to the estimate. Depending on the available data and the characteristics of the populations in the units of analysis, this method can theoretically provide the most accurate results [40, 41].

A study in Bronx County, New York, used GIS to estimate the odds ratios of asthma hospitalizations based on proximity to point sources of environmental risks such as Toxic Release Inventory (TRI) sites and mobile sources of environmental risks such as proximity to highways and major truck routes. The risk of asthma hospitalization near sources of pollution was estimated by constructing buffers around these sources and comparing hospitalization rates within the buffers to those outside the buffers. The buffers around TRI facilities had a radius of one-half of a

mile and other stationary sources of pollution had a radius of one-quarter of a mile. Buffers around highways and major truck routes had a radius of 150 m. Overall, about 66% of the study area was included in the buffers. The study, which used aerial interpolation to estimate the risks of asthma hospitalizations based on proximity, found differential risks depending on the source of pollution. Living within the combined buffers is associated with 30% higher chance of being hospitalized for asthma relative to being outside the buffers. Living within the buffers around TRI sites and stationary sources of pollution is associated with 60–66% higher chance of being hospitalized for asthma relative to living outside the buffers. For highways and major truck routes the risk differential is not nearly as high but the author suggests this may be an artifact of the assumption made that the population around highways and truck routes are evenly distributed within the buffers [37].

An alternative type of proximity analysis is to examine the proximity of sources of environmental risk to point locations associated with sensitive populations of particular interest. Sensitive populations may include asthmatic children or the elderly and the point locations associated with these groups are schools and nursing homes, respectively. This type of analysis was also conducted in the South Bronx, New York, an area with a higher percentage of Hispanic residents (60%) and African-American residents (39%) than New York City as a whole [42]. The study estimated the number and percentage of prekindergarten to eighth grade students who attend schools located within 150 m of a major highway. This is the distance within which concentrations of air pollutants from vehicle traffic are believed to be significantly higher than background concentrations [43], thus justifying its use as a criterion in the analysis. The South Bronx has one of the highest rates of asthmatic children in the country and children are thus considered a sensitive population relative to sources of air pollution [44]. The study estimates that about 18% of students in the prekindergarten to eighth grade category attend schools within 150 m of a highway. The figure for New York city as a whole is only about 8%. This suggests that children attending school in the South Bronx are more likely to be exposed to environmental health risks associated with the high traffic densities associated with highways than children in other parts of New York City [45].

In understanding environmental justice around siting decisions it is important to distinguish between the present socioeconomic characteristics around a source of environmental risk and those characteristics at the time the facility was sited. In some cases, siting decisions were made in neighborhoods with minority or disadvantaged populations, whereas in other cases the neighborhoods change over time after the siting process [35]. Although proximity analyses provide important information and inputs to siting and land use decisions, recent environmental justice literature reviews suggest that the focus of environmental justice analyses should move beyond the kinds of studies described above to include individual environmental hazard exposures and multiple and cumulative exposures to hazards [33, 46].

Beyond proximity analysis, more sophisticated techniques to estimate exposures to environmental risks include distance-decay functions, wind direction and dispersion modeling, and weighted emissions and toxicity [35]. Liu presented an early approach to air quality by using air pollutant dispersion from sources [9]. In the area of air pollution and public health an increasingly popular method to measure exposures is to provide individuals with air pollution monitoring equipment that is carried at all times for a specified period of time. Exposures over time can then be compared to diaries of health symptoms such as asthma attacks, wheezing, and coughing. A study in Bronx County, New York suggests that increased individual exposures to elemental carbon, a pollutant closely associated with vehicle exhaust, is associated with increased wheezing and coughing symptoms among asthmatic children [47]. Exposure analyses of this kind carried out for individuals in different areas can be used to compare exposures across populations with different socioeconomic characteristics. Such methods can also help researchers understand the complex relationships between factors, such as poor nutrition, lack of access to health care, social stress, exposures to multiple environmental hazards, and health outcomes [35], thus enriching the basis for quantitative environmental health risk assessment.

Policy Implications for Risk Assessment and Risk Management

Environmental justice issues have shaped virtually every area of environmental policy and decision

making. The field of environmental impact assessment, which arose with the passage of the National Environmental Policy Act (NEPA) of 1969, began with environmental triggers as initiators of the process with social and economic impacts gradually added once an environmental trigger existed. These social and economic impacts started out as descriptive portrayals of populations and economies, and did not necessarily emphasize imbalances or disparities. In the past decade or so, however, environmental justice issues have emerged not only as major components of an environmental impact statement (EIS) but as triggers as well. Environmental reviews under NEPA and its state versions are critical platforms for environmental justice. The siting of natural gas turbines, described above, is one where environmental reviews became a focal point of the conflict. Not all justice arguments are antidevelopment; some are about development. For example, in 2007, arguments by African-American proponents of a bridge linking two African-American communities in South Carolina, have met with opposition from nonminority groups based on potential environmental impacts from the portion of the bridge crossing a water body [48].

On a broader level, the incorporation of environmental justice within public policy has been sporadic, and has emerged slowly since E.O 12898 was passed. In 2005, the USEPA produced a working draft providing a framework for integrating environmental justice into the strategic plan of 2006–2011 [49]. The strategic planning process encompasses goals and objectives and metrics to achieve them, in accordance with the Government Performance and Results Act (GPRA), submitted annually to the Congress [49: 2]. The working draft on environmental justice indicated that the plan preceding the 2006–2011 strategic plan contained environmental justice commitments only in one place – single goal, Goal 4 for “Healthy Communities and Ecosystems” and a single objective and subobjective within that goal. On November 5, 2005, the EPA Administrator issued a memorandum expanding the number of goal areas in the form of priorities for environmental justice to eight categories: “(1) reduce asthma attacks, (2) fish and shellfish safe to eat, (3) reduce exposure to air toxics, (4) water safe to drink, (5) reduced incidence of elevated blood lead levels, (6) collaborative problem solving, (7) ensure compliance, and (8) revitalization of brownfields and contaminated sites [50].” These

priorities were incorporated into the EPA Strategic Plan produced September 30, 2006 [17: 125, footnote 107].

Process issues are as critical as the substance of environmental justice. The environmental justice movement is marked by leadership of both well-known national environmental organizations and grass roots community and environmental organizations. The relationship between these two levels has been a complex dynamic. The community level as the driver has become a popular theme in the environmental justice movement, and one that was possibly adopted from the broader environmental movement that preceded it. The generation of knowledge and its use for decision making at the local level were identified in the field of public health and termed *popular epidemiology* by Brown [51] and continued for over a decade later as *citizen epidemiology* and *barefoot epidemiology* [52] and *street science* by Coburn [53].

The environmental justice movement has drawn the attention of both national and grass roots groups and organizations. Its affect on policy has gradually evolved in the decades following both the emergence of the environmental movement in the early 1970s and the environmental justice movement that followed. As the environmental area has taken new directions, environmental justice has moved with it. Global problems of deforestation, global climate change, ozone, radiation, and other transboundary problems have justice dimensions. Questions about process will persist with each new issue. What is clear, however, is that environmental justice is now an important component of risk assessment and risk management.

History of Epidemiologic Studies

Epidemiology can be defined as the scientific method used to assess health and its determinants in populations. Central to the method are measures of disease occurrence and study designs for identifying causes of disease and quantifying their strength as causal agents. Because epidemiological studies directly address threats to human health, their findings, when available, have received emphasis in qualitative and quantitative risk assessments.

The utility of epidemiologic data for risk assessment has been widely discussed [1, 2]. Pundits argue that epidemiologic data are not available for many agents and that they are too often flawed by poor quality and biases that cannot be fully controlled [3]. Epidemiologic studies have also been deemed as uninformative for the “weak associations” anticipated for typical levels of exposure to many environmental agents. Proponents of use of epidemiologic evidence, while acknowledging the limitations of observational studies, advance its strengths: the investigation of the effects of actual exposures as received by the population; the characterization of effect across the full range of susceptibility in the population; and, above all, the direct relevance of epidemiologic evidence to public health [4, 5]. Guidelines for the conduct of epidemiologic research relevant to risk assessment have been offered as one solution to strengthening the evidence base [4, 6, 7].

Epidemiologic data can be relevant to each of the four components of risk assessment, as set out in the 1983 “Red Book” of the National Research Council [8]. In particular, the findings of epidemiological studies have proved critical in establishing causation for some of the most important environmental causes of human disease: for example, cigarette smoking, radiation, and asbestos. Principles for evaluating epidemiological evidence within the broader context of other lines of scientific evidence have been developed and applied for decades [9]. Establishing causation is one potential outcome of hazard identification, the starting point in risk assessment (*see Causality/Causation*). The principles originally developed and applied by epidemiologists in evaluating evidence for causation have now been adapted into “weight-of-evidence” schemes. In the absence of

epidemiological findings, hazard identification rests on animal toxicology and consideration of mode of action.

Epidemiologic data indicative of an adverse effect of an agent on health, when available, are strongly weighted in the evaluation of the weight of evidence to determine if an agent presents a hazard. Human data provide direct evidence of a hazard without the need to extrapolate from knowledge of toxicity of analogous agents or from another species. In fact, as we have gained a deeper understanding of the complexity of cross-species extrapolation from animal to man, such extrapolations are viewed with less certainty, unless based in an understanding of human and animal pathways of absorption and metabolism, and of mechanisms of action. Further, epidemiologic studies evaluate the impact of exposures received by the population, including complex mixtures which may not be readily replicable in the laboratory. Epidemiologic research captures the consequences of interactions among agents, and investigations in populations may capture the full range of susceptibility.

If the data collected in an epidemiological study capture dose or a surrogate for dose (generally exposure), then the study may be informative on the nature of the dose–response relationship (*see Dose–Response Analysis*). We consider limitations of the epidemiological data for this purpose and approaches for informatively analyzing epidemiological data for dose–response assessment. Some epidemiological studies, particularly those based in populations, may also inform exposure assessment. Finally, the epidemiological measure, the attributable risk, estimates the burden of disease resulting from a particular exposure. Estimates can be made for those exposed or for the full population comprising both exposed and nonexposed.

History of Epidemiology in Risk Assessment

Even before the formalization of risk assessment, epidemiological studies were generating data relevant to hazard identification, dose–response assessment, and risk characterization. A century ago, the principal focus of epidemiological inquiry was infectious diseases; at the start of the twentieth century in the United States and other industrialized countries, infectious diseases were the leading causes of

morbidity and mortality. As the frequency of these diseases declined and lifespan lengthened, a new group of diseases – so-called “chronic diseases” – emerged as a predominant cause of morbidity and mortality. These diseases included cancer, coronary heart disease, and chronic bronchitis and emphysema, now referred to as *chronic obstructive pulmonary disease* (COPD). In parallel with the epidemic of chronic diseases, the discipline of “chronic disease epidemiology” evolved from the traditions of infectious disease epidemiology, with continued evolution and the development of new approaches.

The causes of cancer, coronary heart disease, and chronic lung disease were the initial targets for chronic disease epidemiologists. By the middle of the century, mortality from lung cancer and heart disease were rising, and chronic lung diseases were increasingly prevalent. The goal of the first wave of studies was identification of causal risk factors, equivalent to hazard identification in risk assessment (see **Causality/Causation**). Many of these studies and their findings are well known: *case-control studies* (see **Case-Control Studies**) and *cohort studies* (see **Cohort Studies**) of smoking and lung cancer, and the Framingham and other cohort studies of the causes of coronary heart disease. The data from these studies were largely analyzed to determine if the putative causal factors were associated statistically with risk for the health outcome. Beginning with the decade of the 1950s, a lengthening list of causes of chronic diseases was identified: cigarette smoking, asbestos exposure (see **Asbestos**), hypertension, and alcohol consumption, for example. These same methods are still used and continue to be informative for identifying new etiologic factors.

As the extent of the epidemiological evidence on particular factors deepened, the need was recognized for an approach for evidence synthesis with the goal of causal inference. Criteria were proposed for this purpose, most notably by Sir Austin Bradford Hill in the United Kingdom and the members of the Advisory Committee to the US Surgeon General, authors of the landmark 1964 Report on smoking and health [10–12]. These criteria were intended to guide an integrated assessment of observational evidence with findings from other lines of research (Table 1). The criteria of consistency and strength of association have proved useful in evaluating the potential role of bias in producing an association. The criterion of coherence addresses the plausibility

of a causal association. The concepts embodied in these criteria are evident in schemes for evidence evaluation used by diverse agencies. The 2004 Report of the US Surgeon General reviews the evolution of these criteria and categories for classifying the level of certainty of causal inference [12].

Early in the development of chronic disease epidemiology, the need for risk characterization was identified. In 1953, Morton Levin published a key paper that described an epidemiological parameter, now generally referred to as the population attributable risk (PAR). By the early 1950s, there was already substantial evidence that smoking was strongly associated with lung cancer risk. Levin reasoned that for a causal factor, it would be useful to know the risk both for an exposed individual and for an exposed population. The PAR estimator proposed by Levin is:

$$PAR = \frac{P_E(RR - 1)}{1 + P_E(RR - 1)} \quad (1)$$

where P_E is the population prevalence of exposure and RR is the relative risk associated with the exposure. The PAR ranges from 0 to 1.0 (0–100%), and its value increases with both P_E and RR . The PAR offers a risk characterization that reflects the exposure distribution and the excess risk from the exposure. It can be generalized to incorporate multiple levels of exposure, each having an associated RR value [13].

The epidemiological data on risk factors often covered multiple levels of exposure; assessment of the relationship between increasing exposure, dose, or a surrogate was an objective analytic strategy in many investigations. Evidence of a dose–response

relationship is supportive of a causal association, not only because a dose–response relationship may be consistent with understanding of the mechanism of action, but because sources of bias become less tenable as an explanation for the association. The approaches used initially involved categorization of exposure into ordered categories. Stratification was used to control for confounding, i.e., the unwanted influence of other factors, and methods were developed for dose–response assessment from stratified data [14].

For many chronic diseases, there are multiple risk factors, and exploration of the dose–response relationship for one may require the simultaneous control of several others. Such control is most conveniently and informatively accomplished using regression models. Beginning in the 1960s, regression models were used for this purpose and subsequently a wide range of models has been developed to accommodate the variety of outcomes and data structures spanned by epidemiological research. For the purpose of risk assessment, some of the most commonly used models are multiple logistic regression, Poisson regression, and the Cox proportional hazards models, used for binary outcomes, incidence, and time-to-event, respectively. More recently developed models handle repeated and correlated events and exposures.

One of the earliest examples of analysis of epidemiological data for risk assessment can be found in the estimation of radiation risks using the cohort study of Japanese atomic bomb survivors. The initial cohort was established within five years of the 1945 bombings and follow-up of blast survivors continues to now. The first excess occurrence of malignancy came with a wave of acute leukemia in both children and adults. By the mid-1950s, there was an evident excess risk, which was dose-dependent.

In a landmark 1957 paper, Lewis assessed the relationship between excess leukemia risk and radiation dose from the blast and concluded that a linear representation was reasonable [15]. Lewis graphically examined accruing data from the atomic bomb survivors that described how risk increased in relation to estimated radiation dose from the blast. He found the relationship to be consistent with linearity and, based on biological considerations, he selected a model without a threshold. As follow-up of the cohort continued, excess risk for solid tumors was also evident. Dose–response relationships have now been repeatedly assessed for cancers [16].

The present Lifespan Study Cohort emerged from the population assembled in the early 1950s. The data have proved to be an extraordinary resource for risk modeling, offering a large population with well-characterized exposure to a single agent and careful follow-up for cancer incidence and mortality from cancer and other diseases. The data have proved to be a rich resource for risk modeling of epidemiological data, as follow-up lengthened and excess solid tumor occurrence was manifest. Increasingly sophisticated statistical models have been used to examine how cancer risk varies with dose and modifying factors such as age at exposure and attained age. Over time, the close estimates have been refined and statistical approaches developed to account for measurement error in these estimates.

Other radiation-exposed groups have also been included in epidemiological studies and the resulting data used for risk models. One notable example is the cohort studies of underground uranium miners who received continuous, but time-varying exposure to radon underground (*see Radon Risk*). The data from 11 cohorts were pooled during the 1990s by the investigators and also by the Biological Effects of Ionizing Radiation (BEIR) VI Committee. Models were developed that allowed radon-related risk to vary by a set of time-related factors: age at first exposure, time since exposure, attained age, cumulative exposure, and exposure rate. Because of the size of the data set (>68 000 participants) and the number of lung cancer deaths (2700), the analyses proved informative, and a relative risk model was developed that estimated risk by time since exposure, with modification of risk by attained age and exposure rate. Data from other radiation-exposed groups have been combined: persons receiving therapeutic radiation and nuclear workers, for example [17].

The “lessons learned” in assessing radiation risk were extended to other exposures, typically involving worker groups exposed to carcinogens at doses sufficient to cause detectable excess cancer risk. Examples include asbestos and lung cancer and mesothelioma in diverse worker groups, and benzene and leukemia. For cancer, epidemiological data from general population studies have also been used in cancer risk assessments: e.g., arsenic and drinking water (*see Arsenic*) and secondhand smoke (SHS) and lung cancer (*see Environmental Tobacco Smoke*). The examples include general population samples with high exposures (arsenic), and typical exposures

Table 2 Recent application of epidemiologic data in risk assessment

Topic	Application of epidemiologic data
Airborne particulate matter (PM)	Background - Under the Clean Air Act, the EPA is required to review the National Ambient Air Quality Standards. Use of epidemiology - A risk assessment was an important component of the review, quantifying the number of premature deaths and hospitalizations due to PM and the number that could be avoided due to attainment of current or alternate standards [18]. - This risk assessment was based on the significant body of epidemiologic evidence relating particulate matter to increased mortality and morbidity risk, including daily time-series studies [19, 20] and long-term cohort studies [21, 22]. - The NMMAPS^(a) was a key piece of epidemiologic evidence, which quantified the relationship between PM and mortality and hospitalizations in the 90 largest cities in the United States.
Methyl mercury	Background - The establishment of a US EPA RfD^(b) for methylmercury was driven by epidemiologic evidence. This RfD^(b) would be used to guide the Agency's future risk management policies. Use of epidemiology - The National Research Council was asked to conduct a risk assessment to help guide the development of the RfD^(b) [23]. - Early data on health effects of methylmercury from accidental poisonings were documented in Minimata Bay, Japan; and Iraq. - Adverse neurodevelopmental effects from contaminated fish consumption were observed in studies from New Zealand and the Faroe Islands, which were key studies used in the development of the RfD^(b) [24, 25]. - The body of epidemiologic evidence regarding the health effects continues to grow, with recent research suggesting a role in cardiovascular disease.
Arsenic in drinking water	Background - In 2001, the US EPA adopted a standard of 10 ppb for arsenic in drinking water under the Safe Water Drinking Act. The standard represented a reduction from the 50 ppb interim standard that had been in place. Use of epidemiology - The US EPA characterized the risk of chronic arsenic ingestion in a 1998 report [26]. - The adoption of a more protective drinking water standard followed a 1999 National Resource Council report evaluating EPA's characterization of risk. - This report and EPA's risk characterization relied on epidemiologic evidence from Taiwan, Chile, and Argentina [27].
Lead	Background - In the 1920s, tetraethyl lead was introduced into automobile gasoline to reduce engine knocking and improve performance. Lead was also commonly used in household paints and other products. Use of epidemiology - The 1970 Clean Air Act required air pollution standards for lead and a gradual phase out of lead in gasoline. This was accelerated through the introduction and widespread use of catalytic converters, which were not compatible with leaded gasoline. In 1978, lead-based paint was banned for use in housing. - Toxic effects of high doses of lead had been known for some time. Regulatory actions led to dramatically reduced blood lead levels among children in the United States.

(continued overleaf)

Table 2 (continued)

Topic	Application of epidemiologic data
	• Epidemiologic research in the late 1970s first identified an association between blood lead levels previously thought to be safe and decrements in neurocognitive function (measured by IQ tests and other scales) [28]. This evidence led the CDC to develop guidelines for treatment of lead poisoning and set a “level of concern” in children of $10 \mu\text{g dl}^{-1}$. • More recent epidemiologic evidence has suggested that neurocognitive effects may occur in children below this concentration, and that there may be no threshold for these effects [29].
Active smoking	Background • In the early part of the twentieth century, cigarette consumption increased dramatically in the United States, including a surge during and after World War II. Use of epidemiology • In the 1950s, a series of case–control studies suggested an association between smoking and lung cancer [30–32] and the first major cohort study, “the British Physicians’ study” was begun [33]. • The accumulated body of evidence was summarized in the landmark 1964 report of the US Surgeon General [11], in which epidemiologic data were considered a key line of evidence. On the basis of this evidence, the report concluded that cigarette smoking was a cause of lung cancer. • Subsequent Surgeon General’s reports on tobacco and health have been released to update the weight of epidemiologic and other evidence and highlight specific diseases (e.g., cardiovascular disease (CVD), COPD), subpopulations (e.g., youth, women, racial/ethnic minorities), and topics such as smokeless tobacco use, smoking cessation, and involuntary smoking. • Epidemiologic data has been used to estimate the attributable burden of disease due to smoking, both in the United States [34] and globally [35].
Secondhand smoke (SHS)	Background • Following the increasing awareness of the harms of tobacco smoke, attention turned to the harms of exposure to SHS. Use of epidemiology • The 1986 Surgeon General’s report identified SHS as a cause of lung cancer and other disease in nonsmokers. This assessment was based on epidemiologic and other lines of evidence [36, 37]. • In a 1992 risk assessment, the US EPA listed SHS as a Group A (known human) carcinogen, making it subject to federal regulation and workplace restrictions [38]. • The risk assessment relied on over 30 epidemiologic studies for cancer alone, along with other lines of evidence to draw its conclusions and quantify the burden of disease due to SHS exposure. According to the report: • “The availability of abundant and consistent human data, especially human data at actual environmental levels of exposure to the specific agent (mixture) of concern, allows a hazard identification to be made with a high degree of certainty.” • Using a pooled relative risk from epidemiologic studies, the report concluded that SHS is responsible for 3000 lung cancer deaths in nonsmokers and 150 000 to 300 000 lower respiratory tract infections in infants, annually. • Since then, updated reports summarizing the epidemiologic evidence and policy implications have been prepared by International Agency for Research on Cancer [39] and the US Surgeon General’s office [40].
Trans fats	Background • Trans fats, produced through the partial hydrogenation of vegetable oils, are used in many baked goods. Use of epidemiology • Intake of trans fats causes inflammation and adverse effects on serum lipids and endothelial cell function [41].

Table 2 (continued)

Topic	Application of epidemiologic data
Global burden of disease	• Evidence from cohort and case–control studies have shown that intake of trans fats increases the risk of coronary heart disease (CHD) “more than any other macronutrient” on a per-calorie basis [41]. • Attributable risk calculation suggests that near elimination of trans fats could result in 72 000–228 000 fewer CHD events annually in the United States [41]. • On the basis of this evidence, the US FDA has required product labeling and some jurisdictions (Denmark, New York) have eliminated the use of these man-made fats.
	Background
	• The World Health Organization’s Global Burden of Disease project attempts to quantify the overall burden of morbidity and mortality and the proportion due to modifiable risk factors in different regions of the world.
	Use of epidemiology

^(b) RfD: reference dose

(SHS). The range of epidemiological data underlying recent risk assessment is broad (Table 2) and relates to both cancer and noncancer outcomes.

Uses of Epidemiology in Risk Assessment

Hazard Identification

As described above, epidemiologic data are typically favored over animal toxicology in assessing the existence of a hazard. In using epidemiologic data for the hazard identification step, interpretation of the evidence is fully parallel to the assessment of the causality of an association between an exposure and an adverse health effect. There are no specific guidelines for interpretation of epidemiologic data in risk assessments that go beyond the conventionally applied criteria for causality. As with the widely applied criteria for causality, there may be disagreement on the proper classification of epidemiologic evidence for the purpose of hazard identification.

The interpretation of negative epidemiologic findings in the hazard identification process is a major

source of disagreement. Studies construed as “negative” typically have findings that are not statistically significant; i.e., the data are statistically consistent with no association between agent and adverse outcome. Such “absence of association”, however, is not equivalent to there being no effect. There are few instances in which epidemiological data have been strongly supportive of no association.

Dose–Response Assessment

For the purpose of risk assessment, characterization of the exposure–response relationship in the range of human exposures is needed. These data may be available from epidemiological studies. For some agents, e.g., SHS and indoor radon data on risks are available in the exposure range of interest, and risk to the general population can be estimated directly; for others, data from exposures above those received by the population may be available from worker groups, e.g., radon exposures of uranium miners, or from persons who have been accidentally exposed, e.g., radiation exposures of the survivors of the atomic

bomb blasts in Hiroshima and Nagasaki. For exposures observed above the range of usual environmental levels, exposure–response relationships estimated at the higher exposures are extended downwards.

Exposure (or dose) may be related to disease risk in a pattern that varies with the temporal profile of exposure and with interactions with other factors, such as age, genetic susceptibility, and environmental factors. Epidemiologic studies rarely include comprehensive data on exposure or dose during the biologically relevant interval, and exposures are often estimated from incomplete data. Consequently, the analyses may not reflect the underlying biological process, and the model applied for data analysis may not give a correct picture of the dose–response relationship.

A further issue is the possibility of error in the exposure indicators, resulting in misclassification of individuals as to their exposure status or level of exposure. Consequently, misclassification of exposure may bias the description of the dose–response relationship. Simple generalizations concerning the consequences of measurement error cannot be made [43]. Random error or nondifferential misclassification tends to blunt the dose–response relationship but other effects may also occur [44]. Nonrandom errors or differential misclassification may increase or decrease the gradient of the dose–response relationship.

In analyzing epidemiologic data to characterize the dose–response relationship, there is *a priori* interest in determining if the dose–response relationship is statistically significant – i.e., whether the null hypothesis of a flat dose–response relationship can be rejected – and in characterizing the shape of the relationship. For the former, the statistical significance of the trend in relation to exposure is of interest. Initially, the shape of the dose–response relationship is explored descriptively, but inevitably statistical models are used to quantify the change in response with increasing exposure. To date, models have been used primarily to characterize the effects of carcinogenic agents; less effort has been directed at noncancer effects, because human data have been less abundant.

For cancer, a number of alternative models have been used to characterize the association between exposure and risk (Figure 1) [8]. Arguments for the biologic plausibility of some of the key alternatives can be made, and use of the alternative models may lead to results with substantially different public

Figure 1 Examples of dose–response models used for carcinogens: (1) linear nonthreshold mode; (2) linear threshold model; (3) sublinear nonthreshold model; and (4) supralinear nonthreshold model [Reproduced from [8]. © National Academy Press, 1983.]

health and regulatory implications. The models differ in the presence of a threshold of exposure that must be exceeded before cancer occurs and in the shape of the relationship between exposure and response. In addition to a linear relationship between exposure and response, sub and supralinear alternatives may also be plausible.

A model of the exposure–response relationship might be estimated from epidemiologic data to extrapolate from higher exposures, where observations have been made, to the lower levels at which general population exposures occur, or to describe the exposure–response relationship quantitatively at typical exposures. Steenland and Deddens [45] supply some practical guidance on modeling exposure–response relationships for risk assessment. They favor simple parametric models. In modeling epidemiologic data, *a priori* biologic considerations should determine the choice of the model to the extent possible. For example, a linear relationship without a threshold would be consistent with an exposure that caused irreparable genetic damage with a single “hit” from the agent. Genetic injury from α particles released by deposited radionuclides, “internal emitters”, is an example [46]. For some agents, modeling approaches have been established that have a biologic rationale and historical precedent. For ionizing radiation, a linear no-threshold relationship has long been assumed [17]. The assumption that there is no threshold is also protective of public health as it implies that no level of exposure is safe.

Epidemiologic data may also be fit with alternative models of the exposure–response relationship if there is uncertainty about the most appropriate shape. Model fit may be used to guide the selection of the “best” model. However, epidemiologic data are rarely sufficiently abundant to provide powerful discrimination among alternative models, and sample size requirements for comparing fit of alternative models having different public health implications may be very high [47, 48]. For example, Lubin and Gail [48] calculated sample size requirements for testing if the exposure–response relationship for radon and lung cancer differed by 100 percent from that observed in underground miners. The calculations indicated that approximately 10 000 participants would be needed in a case–control study if sufficient power were to be achieved.

Exposure Assessment

For the purpose of risk assessment, information is needed on the full distribution of exposures in the population. Measures of central tendency may be appropriate for estimating overall risk to the population, but reliance on central measures alone may hide the existence of more highly exposed persons with unacceptable levels of risk. For example, the average concentration of indoor radon in US homes is about 1 picocurie per liter (pCi l^{-1}) of air (a measure of radioactivity) [46]. About 5% of homes are above the EPA guideline for remedial action of 4 pCi l^{-1} and some homes have concentrations of 1000 pCi l^{-1} or more. Focusing solely on control measures to lower the average exposure would obscure the need to find the homes in the tail of the distribution which have unacceptable levels. The EPA has recognized the need to characterize the upper end of the exposure distribution in its exposure assessment guidelines [49].

To date, epidemiologic data have not played prominent roles in exposure assessment. However, epidemiologic-based surveillance and screening approaches have the potential to provide important insights into population exposures. For example, blood lead surveillance has been a critical part of understanding the risks of environmental lead. Population-based survey data such as the National Health and Nutrition Examination Survey (NHANES) may be available on exposures, often describing contact with sources, e.g., exposure to

smokers as an indicator of exposure to SHS [50], or levels of biomarkers, e.g., cotinine [40].

Risk Characterization

Risk characterization represents the final step in risk assessment. This step puts the risk in perspective for risk managers and the public. During this phase, the data on exposure are combined with the exposure–response relationship to estimate the potential risk posed to exposed populations. The risk characterization becomes the fulcrum for decision-making and the basis for communication with stakeholders [51]. Epidemiologic studies may provide a direct risk characterization if the findings can be linked to a specific population and the exposure assessment component of the study is sufficient.

The PAR and years of life lost, both measures of the burden of imposed morbidity or mortality, are appropriate parameters for risk characterization. The US Centers for Disease Control and the World Health Organization (WHO) have used such measures to estimate risk from the major modifiable causes of death and disease in the United States and globally [34, 52]. In the United States for example, Mokdad *et al.* estimates that about 800 000 deaths annually are attributable to tobacco use and poor diet/physical inactivity [34]. Similarly, WHO’s Global Burden of Disease project estimates the number of avoidable deaths, years of life lost, and disability adjusted life years lost. The latter two indicators take into account the age of death and onset of disease [52].

Strengthening the Use of Epidemiology

The continued strengthening of the quality of epidemiologic studies should lead to its larger role in risk assessment. Approaches are available to quantify and adjust for measurement error, and flexible statistical modes may be incorporated to minimize potential confounding. The continued development of analytical laboratory methods to measure low-level dose biomarkers in human tissues, along with the use of flexible statistical models and meta- or pooled analyses, will allow for improved precision of risk estimates and a more precise exploration of dose–response relationships. Such improvements would minimize the need for the host of default uncertainty factors typically incorporated into human health risk assessment.

Minimizing Bias and Confounding in Epidemiologic Studies

A principal challenge in the conduct and interpretation of epidemiological findings is to minimize the presence of bias and *confounding* (see **Confounding**). *Confounding* may result in a distortion of the true exposure–disease relationship arising from the presence of a third factor, which is both associated with the exposure and an independent cause of the disease. Failing to address confounding through the study design or in the data analysis may result in biased estimates of the association between exposure and disease. *Bias* refers to “systematic error in the design or conduct of a study” [53]. Such an error can arise during sample selection (selection bias) or data collection (information bias), and will result in systematic departures from the true relationship. This is in contrast to *random* error, which results from the random selection of a sample of the population, and which can be characterized quantitatively through the use of confidence intervals.

Several methods exist to assess the extent and implications of bias or uncertainty. Random sampling error is characterized through the use of confidence intervals, which describe a range of estimates that captures the true value with some degree of certainty. Confounding in epidemiological studies is addressed through either restricting the sample population to only one level of a potential confounder (e.g. non-smokers) or through statistical methods for deriving adjusted estimates. It is considerably more difficult to ensure that bias (or systematic error) is minimized in epidemiological studies. Some approaches include the use of validation studies or sensitivity analyses, to examine both the potential for bias and direction of impact on the relationship under study.

Validation studies can be conducted to quantify and adjust for measurement error, assuming the presence of a gold-standard measure [54]. For exposure measurement error, the gold-standard is often a biological marker of dose. Such studies can be conducted on a subset of the study population to adjust exposure assessment for the full sample. Sensitivity analyses are useful approaches to quantify the impact and direction of other potential biases. Flexible statistical modeling approaches, including generalized additive models and nonparametric regression, can be used to reduce residual confounding and allow for fewer assumptions when estimating the shape

of dose–response relationships, specifically when dealing with large sample sizes [54].

Combining Evidence

Meta-Analysis. Epidemiologic studies may have limited power to address the effects of exposures in a range that would be of concern for the general population. Meta-analysis (see **Meta-Analysis in Nonclinical Risk Assessment**) has been used to summarize data for the steps of hazard identification and dose–response assessment. It has been used increasingly as a tool for summarizing experimental and observational studies [55] and methods for epidemiologic data have been extensively reviewed [56, 57]. Meta-analysis provides a potentially more informative interpretation of the evidence when sampling variation and small studies have obscured the status of the evidence. Thus, statistical power for detecting an effect is gained, and dose–response relationships can be described with greater precision. Meta-analysis has now been applied to a number of environmental agents including, for example, SHS [38], electromagnetic radiation [51], nitrogen dioxide [58], and indoor radon [59].

Use of meta-analysis to characterize the relationship between indoor air pollution and lung cancer risk is instructive. A number of case–control studies on indoor radon and lung cancer were initiated over the last decade to estimate the risk of indoor radon directly and to avoid the uncertainty arising from extrapolation of risks from underground miners to the general population. Sample size needs of these studies were not fully appreciated as they were designed [48], and a number of studies have had null findings but wide confidence intervals on effect estimates. Lubin and Boice [60] carried out a meta-analysis of eight case–control studies that were completed as of mid-1996. Although five of the individual studies were considered to be “negative”, the overall effect of indoor radon on lung cancer was statistically significant and the dose–response relationship was fully compatible with observations in miners.

Pooled Analysis. Pooled analysis refers to the analysis of individual-level data from multiple studies, unlike meta-analysis which aggregates data at the study level. This approach has been informative in characterizing dose–response relationships for radiation and cancer and for evaluating modifiers of

these relationships. Pooled analyses on radiation risks have been published for nuclear workers [61], underground miners [46, 62], and for women who received repeated fluoroscopy in the management of tuberculosis [63].

The analyses of data from cohort studies of radon-exposed underground miners are illustrative. Data on dose–response relationships can be obtained from individual studies, but variation exists among the studies in the magnitude of the estimated excess risk. To characterize the dose–response relationship between indoor radon and lung cancer, the BEIR IV Committee obtained data from four epidemiologic studies, including about 22 000 subjects who had experienced 350 lung cancer deaths during follow-up. The data were analyzed with regression methods to characterize the dose–response relationship. A linear model was used, and the risks were found to decline with increasing time since exposure and increasing age at observation. With the completion of additional studies, the data available for pooling expanded to 68 000 men and 2700 lung cancer deaths drawn from 11 cohorts [62]. In the resulting model, lung cancer risk was further found to increase with lower exposure rates; i.e., at a given level of cumulative exposure those receiving exposures at lower rates have higher risk. Because the data base included smoking information for a substantial number of participants, risks were also estimated separately for smokers and for nonsmokers.

Ranking Quality/Utility of Epidemiologic Evidence for Risk Assessment

In using epidemiologic data in risk assessment, interpretation of the evidence is fully parallel to the assessment of the causality of an association between an exposure and an adverse health effect. This assessment of causality is a judgment based on an evaluation of all available evidence. The conventional set of criteria most often referred to in the context of assessing causality was proposed by Hill [10]. These criteria, which include the strength of association, consistency between studies, and biological plausibility, were intended as guidelines, not hard and fast rules. There are no specific guidelines for interpretation of epidemiologic data in risk assessments that go beyond these conventionally applied criteria. However, several frameworks for classifying epidemiologic evidence for use in risk assessment

have been presented. A classification for ranking epidemiologic studies for use in hazard identification and dose–response assessment has been proposed by Hertz-Picciotto [4] and modified by van den Brandt *et al.* [54]. This classification scheme is based on both the internal validity (i.e., extent of potential bias and confounding) of the study and the characterization of exposure and dose–response. Swaen [64] describes a classification scheme which also focuses on the internal validity of the study, including the use of an appropriate study design, minimizing bias and confounding, and reducing measurement error in the exposure and outcome.

Summary

Epidemiological evidence has a central role in risk assessment, when available. It can contribute to all elements of a quantitative risk assessment. Epidemiological data have the notable strength of being based on the “right” species, “real-world” exposures, and often the full range of susceptibility. Observational data often have inherent limitations, but strategies are available to handle them. The development of radiation risk models from epidemiological studies and the use of the models in quantitative risk assessment have set a risk assessment paradigm grounded in epidemiological research.

Environmental Health Risk

Homeland Security and Transportation Risk

Transportation infrastructures (*see* **Managing Infrastructure Reliability, Safety, and Security**) make attractive targets of intentional harmful attacks because of their visibility, accessibility, and capacity to carry large numbers of commuters in a relatively confined space. Historical data on terrorist incidents worldwide show that approximately 60% of attacks have targeted the transportation sector [1]. Terrorism can be generally defined as “premeditated, politically motivated violence or deliberate threats of violence against noncombatant targets by subnational groups or clandestine agents, usually intended to influence an audience” [2].

The coordinated hijackings and deliberate crashes of airplanes into the World Trade Center in New York and the Pentagon in Washington, DC, on September 11, 2001, dramatically heightened both the perception and the reality of the threat terrorism poses to public transportation systems. This event, unprecedented in the annals of terrorism, focused national attention on aviation security in the United States (*see* **Near-Miss Management: A Participative Approach to Improving System Reliability**). However, maritime and surface transportation systems also continue to be vulnerable to attacks by terrorists who seek to attract publicity, inflict high numbers of civilian casualties, and cause political and economic disruption. The London subway bombings on July 7, 2005, provided more recent and prominent evidence of this continuing vulnerability.

Methodologies for Assessing and Managing Transportation Security Risks

The US government responded to the September 11, 2001, attacks by elevating terrorism to the top of the country’s national security and law enforcement agendas. Existing and newly created federal agencies now face the daunting challenge of determining how to allocate finite resources to manage risks while addressing threats and enhancing security across all key transportation modes: aviation, maritime, rail, pipelines, highways, trucking, and busing, and public mass transit.

The Transportation Security Administration, created in November 2001 as part of the Aviation and Transportation Security Act, has pledged to follow a systems-based risk-management approach that incorporates the three key elements of all risk assessment methodologies: threat, vulnerability (including criticality), and consequence (*see* Figure 1).

A threat assessment (*see* **Use of Decision Support Techniques for Information System Risk Management; Simulation in Risk Management; Reliability of Consumer Goods with “Fast Turn Around”**) identifies and evaluates potential threats on the basis of factors such as capabilities, intentions, and past activities. A vulnerability assessment recognizes weaknesses that may be exploited by identified threats and suggests countermeasures to address those weaknesses. A criticality assessment evaluates and ranks assets and functions in terms of specific criteria, such as their importance to public safety and the economy, as a basis for determining which structures or processes are relatively more important to protect from attack [3]. The characterization of risk is completed through analysis of the consequences associated with the partial or total loss of critical assets because of intentional harmful attacks.

Threat Assessment

Terrorism presents an “asymmetric” threat in which terrorists employ surprise and relatively low-cost weaponry to inflict or threaten catastrophic damage on large populations and property, causing fear, panic, and disruption. Assessing such threats is more difficult and often derives from assumptions about the capability and intent of terrorist organizations. These assumptions may include the value the threat places on certain assets for political or morale purposes, the threat’s ability to gain access to critical assets, and the disruptive or destructive capability of the weapons the threat may employ (including threatening statements, hoaxes, and real weapons of mass destruction) [4].

In March 2002, the US government established the Homeland Security Advisory System to provide a national framework for communicating the nature and degree of terrorist threats between government officials and citizens. The system uses color codes to convey whether there is a severe (red), high (orange), elevated (yellow), guarded (blue), or low (green)

Figure 1 Risk-management cycle

risk of terrorist attacks. In assessing a threat, system managers consider a variety of questions:

- Is the threat credible?
- Is the threat corroborated?
- Is the threat specific or imminent?
- How grave is the threat?

With regard to specific transportation assets, public agencies responsible for assessing and managing security risks may apply related criteria to make an informed judgment [4]:

- **Existence** – Is there a group or an individual that is known to or potentially could be operating within the jurisdiction with the capability to create or use a particular weapon or tactic?
- **History** – Has the jurisdiction experienced any past terrorist activity?
- **Intent** – Are there credible advocacies or threats of force or violence, or acts, or preparations to act, evidencing the intent to create or use a weapon or tactic?
- **Capability** – Is there credible information that a specific group or individual possesses the needed training, skills, finances, and access to resources to develop or acquire a particular weapon or tactic?
- **Target** – Is there credible information indicative of preparations for specific terrorist operations against a critical asset?

Vulnerability Assessment

A vulnerability assessment involves two key steps: (a) the identification of critical transportation assets and (b) evaluation of the vulnerability of critical

assets to one or more presumed threats. Identification of critical assets typically begins by organizing a team of experienced staff most familiar with the transportation assets under assessment. For highway assets, for example, such a team might include operations and maintenance staff, design and construction engineers, traffic engineers, and field personnel. Transportation assets can be organized into four major categories: infrastructure, facilities, equipment, and personnel. By considering the mission of the transportation system and of the responsible government agency, the study team can develop a list of key assets that enable achievement of the mission. An assessment of highway transportation assets might yield a list similar to Table 1.

Judgment of the relative importance of assets proceeds on the basis of critical factors such as casualty risk, potential effects on government continuity and emergency response, the military importance of the asset, economic impact, and the availability of alternative resources to perform an asset's primary function.

At least three factors influence the vulnerability of a particular transportation asset: (a) visibility and attendance, (b) access, and (c) site-specific hazards. Vulnerability increases with greater awareness of the existence of an asset and the number of people typically present, as well as with greater availability of an asset to ingress and egress by a potential threat element. Vulnerability is further increased by the presence of materials on site that have biological, nuclear, incendiary, chemical, or explosive properties in quantities that would expend initial response capabilities if compromised [4].

Numerical scales have been developed to assess both the criticality and vulnerability of transportation

assets, but simpler ordinal scales are also used. For example, the Federal Transit Administration grades the accessibility of assets on a five-letter scale as depicted in Table 2.

The vulnerability of a transportation asset also depends on the specific nature of the threat. Attacks with explosives or incendiaries have characteristics that differ from attacks involving acts of force or the use of chemical, biological, or radiological agents. A recent report on security measures for ferry systems [5] identified 11 different security locations within ferry systems and considered the vulnerability of each area to different types of threats. For example, Table 3 presents hypothetical relative vulnerabilities of security areas to delivery of an improvised explosive device (IED) by various modes.

Consequence Assessment

The specific consequences of attacks on transportation assets depend on the nature of the attack and the impact of the loss of the asset. Consequences can include loss of life and property associated with the attack, as well as loss of infrastructure needed to support economic activity, military deployment, or the ability to respond effective to other emergencies [4].

Results from the criticality and vulnerability assessments assist risk analysts in focusing the consequence assessment on scenarios expected to pose the greatest risks to transportation security. The most severe consequences usually derive from attacks on the most critical and vulnerable assets – the so-called Quadrant I assets in the criticality and vulnerability matrix (see Figure 2).

Figure 2 Criticality and vulnerability matrix

Table 1 Examples of critical highway transportation assets^(a)

Infrastructure	Facilities	Equipment	Personnel
Arterial roads	Headquarters buildings	Hazardous materials	Contractors
Interstate roads	Traffic operations centers	Roadway monitoring	Employees
Bridges	Regional complexes	Signal/control systems	Vendors
Overpasses	Maintenance stations	Messaging systems	Visitors
Barriers	Ports of entry	Vehicles	
Roads on dams	Chemical storage areas	Communication systems	
Tunnels	Fueling stations

Table 3 Hypothetical relative vulnerabilities of security areas to IEDs

Location	IED delivery mode					
	Person	Vehicle	Vessel	Artillery	Mine	Overhead
Beyond site boundary	M	M	N/A	L	N/A	**
Facility perimeter	M	H	N/A	L	N/A	**
Vehicle parking	H	H	N/A	M	N/A	**
Vehicle holding	M	H	N/A	L	N/A	**
Passenger waiting area	H	M	N/A	L	N/A	**
Terminal operations	M	L	N/A	H	N/A	**
Adjacent to ferry (shore)	H	L	N/A	H	N/A	**
Adjacent to ferry (water)	M	L	H	H	H	**
Onboard (unrestricted)	H	L*	N/A	L	N/A	**
Onboard (restricted)	M	H*	N/A	L	N/A	**
In transit	L	L	H	H	M	**

H: high; M: medium; L: low; and N/A: not applicable for this security area

*Assumes that onboard cargo area, including vehicle storage area, is restricted

**Assumes similar vulnerability among security areas without specification of a particular mode

Risk is informally defined as probability times consequence. Thus, a complete risk analysis weighs the estimated frequency of a threat, as well as its estimated consequences. Such estimates can be made using either qualitative or quantitative methods. In either case, the goal is to identify the attack scenarios posing the greatest transportation security risks. Subsequently, the key task for risk managers is to determine how overall security risk should be reduced through the deployment of countermeasures that either reduce the chance of an attack or mitigate its consequences.

Qualitative versus Quantitative Risk Analyses

Because of the difficulties in quantifying key components of threat, vulnerability, and consequence assessments, analyses of transportation security risk typically employ qualitative methods in making judgments about the relative magnitudes of various risk scenarios. Although it is often impractical to apply quantitative risk analysis to a large number of risk scenarios [1], such methods may be more readily used after an initial screening to identify the scenarios of greatest concern.

Some elements of a transportation security risk analysis are relatively amenable to quantitative treatment. Databases on terrorist attacks are maintained by the US government, nonprofit research organizations such as the Mineta Transportation Institute and the RAND Corporation, and private companies [2, 6].

These databases support research on the targets of terrorist attacks and the weapons and tactics used by the perpetrators. For example, Figure 3 summarizes the distribution of targets in attacks on public surface transportation systems during the 80-year period from 1920 to 2000. Buses, subways, and trains are the most popular targets, collectively involved in more than half of the attacks in this period. Similarly, Figure 4 shows that bombings predominate as the tactic of choice in attacks on public transportation systems, accounting for 60% of all such incidents from 1920 to 2000 [2].

Historical data on events involving the use of various types of weapons and tactics can also be used in quantitative assessments of the consequences of future attacks. Table 4 lists the typical number or range of casualties incurred in attacks involving threats available or potentially available to terrorists. Ongoing concerns about the risks of terrorist attacks involving chemical, biological, radiological, or nuclear (CBRN) agents stem from the great destructive force of these weapons.

Transportation Security Risk Management

Risk management involves two key steps: (a) determining which risks identified in the risk assessment process require mitigation and (b) developing and implementing plans or actions that are required to ensure that the selected risks are reduced to more acceptable levels. Protective security measures are

Figure 3 Targets of attacks on public surface transportation systems (1920–2000)

actions intended to reduce vulnerability, deny an adversary opportunity, or increase response capacity during a period of heightened alert [7].

Countermeasures to protect critical assets such as transportation infrastructure commonly involve site-work, building/structure, detection, and procedural elements [4]:

- *Site-work* elements address the area surrounding a facility or an asset and may include perimeter barriers, landforms, and standoff distances.
- *Building and structure* elements are directly associated with facilities and structures and may include walls, doors, windows, and roofs.
- *Detection* elements include closed-circuit television, motion detectors, alarms, and weapon detectors, as well as any guards needed to operate this equipment or to perform similar functions.
- *Procedural* elements refer to the protective measures required by regulations, policies, or plans that provide the basis for developing the other elements.

Security countermeasures are intended to provide target systems with additional capabilities in terms of deterrence, detection, and defense [4]. Deterrence countermeasures are effective when a potential aggressor is dissuaded from attacking an asset because of a perceived increase in the risk that the attack will fail or that the aggressor will be captured. The success of deterrence will vary depending on the asset's attractiveness, as well as the sophistication and objectives of the aggressor. An effective detection measure provides added capabilities to sense an act of aggression, assess the validity of the detection, and communicate the appropriate information to a response force. Defensive measures protect an asset by preventing or delaying an aggressor's movement toward the asset or by shielding the asset from the effects of tools, weapons, and explosives.

For example, in compiling a list of possible countermeasures for critical bridges, one state department of transportation identified the following items [4]:

- increased patrol by law enforcement;
- increased patrol by coast guard;

Figure 4 Tactics used against public transportation systems (1920–2000)

Table 4 Specific threat types and historical casualty rates^(a)

Specific threat type	Historical casualties per incident (number of people affected)
Nuclear	50 000
Chemical	5000
Biological	1500–5000
Radiological	1500–5000
Explosives/incendiary	50–3000
Fire arms/armed assault	10–100
Hijack/hostage	10–100
Cyber/information security	Unknown

^(a) Reproduced from [7]. Federal Transit Administration, 2006

- rapid removal of abandoned vehicles;
- barriers around bridge piers;
- construction of barriers around cable anchors of suspension bridges;
- higher level of identification for personnel working on or around affected bridges;
- security cameras, monitors, and related software to monitor sensitive areas;

- removal of vegetation to provide clear lines of sight.

Making rational decisions among options for managing transportation security risks requires estimation of the capital, operating, and maintenance costs of candidate countermeasures, as well as a comparative evaluation of their effectiveness in reducing either the potential for or consequences of attacks on assets given specific threats and vulnerabilities [4].

One recently published cost–benefit analysis (*see Environmental Performance Index; Environmental Risk Regulation; Global Warming; Operational Risk Modeling*) [8] compared several alternative device configurations for aviation-checked baggage security screening:

- explosive detection systems;
- explosive trace detection;
- dual energy X ray;
- backscatter machines.

The study considered single-device configurations, as well as two-device scenarios in which a second

device is used to screen all bags signaling alarms when passed through the first device. Configurations were evaluated with respect to the expected direct cost per checked bag and the expected number of successful threats per one billion checked bags. Results indicated that, for the current security environment, single-device use of backscatter machines is superior to other configurations in terms of expected cost and number of successful threats.

Such cost–benefit analyses can assist risk managers in allocating resources most effectively to enhance transportation security.

Current Perspective on Transportation Security

National transportation systems in developed countries, such as the United States, Japan, and member nations of the European Union, are vast interconnected networks of diverse modes. Key modes include aviation, maritime traffic, and surface transportation (e.g., highways, rail, and transit). For example, the US transportation system moves over 30 million tons of freight and supports approximately 1.1 billion passenger trips each day [3]. Because of its diversity and size, a national transportation system is vital to a country's economy and national security.

Transport vehicles and facilities have frequently been targets of terrorist attacks, hijackings, and sabotage around the world. Transportation systems possess characteristics that make them especially vulnerable to terrorism: the capacity to carry millions of people daily in enclosed spaces; elements with symbolic, as well as strategic, value; both military and key civilian functions; and an open and distributed infrastructure that complicates efforts to deploy effective security measures [9].

Transportation assets are not only targets of terrorist attacks, but can serve as a weapon or delivery mechanism, as demonstrated dramatically in the attacks in the United States on the World Trade Center and the Pentagon. Regardless of the number of casualties involved, attacks that disrupt public movements can seriously impact a region's economy and can erode the public's faith in the government's ability to provide basic protections to its citizens [2].

The specter of international terrorists with more ambitious goals, as well as the resources to plan and launch increasingly destructive attacks, has established a new context for transportation security and

planning. Governments of countries that perceive an elevated level of threat are investing considerable resources to implement comprehensive programs to enhance security in all key modes of transportation. These efforts include formal risk assessment and management efforts. Recent initiatives in the United States serve as an illustrative case study.

Aviation

Airplanes were the weapons of choice in the devastating terrorist attack of September 11, 2001. Consequently, recent efforts to enhance transportation security – particularly, such efforts in the United States – have focused on the aviation industry. A new federal agency, the Transportation Security Administration, was created to provide federal control of passenger and baggage screening operations. All checked baggage is now screened using explosive detection systems. Access restrictions to planes and airport facilities have been implemented by adding security personnel, access controls, and screening measures. Expanded security operations include more random searches throughout airports, verification of employee identities, and more comprehensive background checks on passengers and employees [9]. Air marshals provide in-air security on high-risk flight routes, and measures such as cockpit doors with locking mechanisms have been introduced to improve protection of the flight officers.

Compared with other modes of transportation, air travel possesses some characteristics that facilitate implementation of security measures. Airplanes are housed in fairly closed and reasonably controlled locations. Also, airport terminal access to airplanes is controlled by relatively few entry points [2]. Recent initiatives have significantly improved aviation security and lowered the risk of hijackings or sabotage. However, concerns remain about vulnerabilities in the handling of air cargo and in procedures at smaller airports serving general aviation. Research is ongoing to develop new aviation security technologies, such as passenger profiling systems, bombproof cargo containers, and better screening tools for explosives and other materials [9].

Maritime Traffic

Shipping and ports are vital elements in the economic and military activities of most countries in

the world. The extensive size, open accessibility, and metropolitan location of most ports ensure a free flow of trade but present great challenges to effective monitoring and control of traffic through the ports. Large ships, such as oil tankers, warships, cargo ships, or cruise liners, are vulnerable because of their strategic value, visibility, slow speed, and limited maneuverability. Critical infrastructures located along the coast or on inland waterways – including bridges, power plants, and oil refineries – have few protections against approaching ships carrying explosives or other harmful materials [9].

Because of the urgent need to address aviation vulnerabilities after the September 11, 2001, attacks, the United States has placed secondary emphasis on strengthening maritime security. However, initial risk assessments were conducted for all ports to identify critical infrastructure and key assets, assess vulnerabilities, develop mitigation strategies, and highlight best practices. Protection has been improved by deploying fences, surveillance cameras, and additional personnel to guard facilities, as well as by limiting vehicular traffic around seaports. The coast guard has increased patrols of waterways, coastline, ports, and coastal facilities. Intelligence agencies have created large databases to track cargo, ships, and seamen in a search for anomalies that could be indicators of terrorist activities [9].

Perhaps the most serious terrorist threat to maritime security involves the smuggling of explosives or CBRN weapons into a country using cargo containers. To address this threat, the American government has launched a container security initiative with international cooperation. The initiative strategy is to use automated information to identify and target high-risk containers, detection technology to quickly screen high-risk containers, and smarter, tamper-proof containers to reduce susceptibility to misuse [9].

Surface Transportation

Surface transportation comprises a diverse array of long-distance passenger and freight vehicles and facilities, mass transit vehicles and facilities, and related infrastructures. Elements include trains, trams, subways, buses, trucks, railway lines, highways, stations, depots, control facilities, bridges, and tunnels. In virtually any country of the world, this complex network of systems is absolutely essential to support daily life and economic activity [9].

Terrorists have a history of attacking such surface transportation assets as cars and buses, typically with explosives or firearms. Indeed, about one-third of all terrorist attacks worldwide target surface transportation systems [9]. However, recent terrorist activities reflect a shift from isolated bombings, hijackings, and hostage-taking toward inflicting higher numbers of civilian casualties, more extensive property damage, and increasingly devastating effects on economies [10].

From this perspective, surface transportation assets generally have low attractiveness to terrorists, relative to other targets, because the potential for casualties is fairly modest. Transit and rail systems are regarded by law enforcement agencies to be among the most likely targets. The principal threats against highway physical assets are explosive attacks on such key links as bridges, interchanges, and tunnels. The most vulnerable highway facilities are those that play important regional and strategic roles, are difficult to replace, and would cause maximal disruption in case of attack [10].

In the United States, efforts to enhance surface transportation security have generally involved improvements to the physical security of the most critical assets and the control of access to these assets. Perimeter security measures include additional fences and barriers, surveillance cameras, intrusion detection systems, and better lighting. Many organizations have employed additional security staff and launched public awareness campaigns to deter and prevent terrorist attacks [9].

Because of the need for openness and accessibility at thousands of entry points, the wide geographic distribution of assets, and the static nature of some routes, complete protection of surface transportation infrastructure is simply not feasible. Better physical security and public vigilance, as well as an increased security presence, will not prevent all possible attacks. Effective security strategies must also seek to minimize loss of life and disruption through planning, coordination, and training involving transportation operators, law enforcement authorities, and emergency response organizations [9].

Conclusions

Any particular terrorist attack is essentially a low-probability, high-consequence event (*see Near-Miss Management: A Participative Approach to*

Improving System Reliability). Therefore, strategies to mitigate risks to transportation assets should differentiate among priorities largely on the basis of target criticality [10]. Both the scale and nature of transportation systems necessitate that a reasonable degree of risk must be accepted, even for critical assets, because complete mitigation is not feasible. No security system can stop determined terrorists from deploying explosive, biological, or chemical weapons in public places [2]. However, effective countermeasures increase the difficulty of executing a terrorist attack, as well as the chances of detecting and identifying the perpetrators, minimize casualties and disruptions, reduce panic, and reassure an alarmed citizenry. Formal methodologies for assessing and managing risks to transportation security provide a valuable conceptual structure and practical tools for allocating resources in cost-effective ways to improve public safety.

DUANE L. STEFFEY

Hormesis

A central biological concept is the dose–response relationship (*see* **Dose–Response Analysis**) upon which the fields of toxicology and risk assessment are built. Assumptions concerning the nature of the dose–response affect the questions that scientists ask, how studies are designed, including the number and the spacing of doses, risk assessment procedures that are employed by agencies such as EPA and FDA, as well as cost–benefit assessments (*see* **Cost–Effectiveness Analysis**) that often guide the plethora of decisions upon which health systems and environmental regulations are based. In short, society is enormously dependent on the qualitative and quantitative accuracy of dose–response models, particularly when the likely exposures are outside (i.e., usually lower) the range at which the predictive biological models were tested. This is certainly the case for the vast majority of environmental agents.

Historical Foundations of the Dose–Response

Society has looked to the fields of toxicology and risk assessment for guidance on what is the nature of the dose–response, especially in the low-dose zone. For nearly eight decades, the international scientific community has offered a consistent and unwavering judgment that the most fundamental dose–response is that of the threshold model, with below-threshold responses being assumed to be indistinguishable from unexposed control-group values. This basic conclusion of the scientific community has led to the establishment of the threshold dose–response model (*see* **Threshold Models**) as the conceptual centerpiece for hazard assessment testing and bioassay designs, for uncertainty factor application in assessing risks from chemicals and drugs and for how to design preclinical investigations and clinical trials (*see* **Randomized Controlled Trials**) for the pharmaceutical industry. As discussed further below, the basis of this “firmly believed” conclusion has recently been undermined by several studies that have surprisingly provided the first ever large scale direct testing of the validity of the threshold dose–response model. The threshold dose–response model poorly predicted responses in

the low-dose zone (i.e., below threshold) for chemical and pharmaceutical agents [1–3].

Despite the current erosion of its credibility to accurately predict responses below the toxicological threshold, the threshold dose–response model was useful in the early part of the twentieth century in predicting toxicity at high doses and such dose–responses often seemed to display thresholds below which no toxicity occurred [4]. This threshold dose–response relationship had enormous practical value, since below-threshold exposures suggested that toxicity would not be a concern. Guided by the threshold dose–response model, the goal of governmental hazard assessment activities became one of defining the toxic dose–response and estimating the highest safe dose or the toxic threshold. On the basis of this frame of reference, toxicology quickly became a high dose–few dose discipline. The threshold model immediately became valuable in assessing toxic doses in the occupational domain and useful in establishing exposure standards; it was also useful in estimating doses that would eliminate pests, such as disease-transmitting insects. Regulatory agencies, therefore, focused on reliably estimating toxicological thresholds since below that dose, safety was assumed.

During the middle and latter decades of the twentieth century, agencies such as the FDA and EPA veered away from the threshold model when addressing low-dose cancer risks; such agencies decided to adopt a linear at low-dose modeling strategy, mostly to assuage a strong societal preoccupation with fear of cancer rather than a belief, or a data-based conclusion, that carcinogens did not act via a threshold scheme as well. This decision to accept linear at low-dose modeling for cancer risk assessment has been problematic ever since. The most important limitation of this modeling strategy is that it simply cannot be practically tested, that is, validated, at risks of relevance to society (i.e., less than one person adversely affected in a population of 1000). Since this model cannot be practically tested at even moderately low risks to society, its predictions were required to be either believed or at least accepted as accurate. However, since the implementation of these beliefs within society was enormously costly, the adoption of the linear-no-threshold (LNT) model for carcinogens has been a source of great controversy and public policy assessment.

Substantial debate over the past 30 years in the toxicology and risk assessment communities has

therefore focused on whether the threshold or the LNT model was most likely correct. While debate has continued, there has been no practical way to resolve this toxicological question since epidemiological methods are too insensitive, while toxicological methods would require enormous resources. For example, in the famous FDA megamouse study of the late 1970s even 24 000 mice were too few to answer the question since risks could only be resolved to the 1/100 risk level, thereby yielding the name *ED01 study* [5].

While the toxicological community thought the principal dose–response debate was over threshold *versus* LNT models, this proved to be the wrong question. Over the past decade, sufficient data have emerged to suggest that the most fundamental model in the biological and biomedical sciences is neither the threshold or LNT model, but rather the hormesis dose–response model, which is characterized by a low-dose stimulation and a high-dose inhibition as seen in either inverted U- or

Figure 1 (a) The most common form of the hormetic dose–response curve depicting low-dose stimulatory and high-dose inhibitory response, the β - or inverted U-shaped curve. Endpoints displaying this curve include growth, fecundity, and longevity. (b) The hormetic dose–response curve depicting low-dose reduction and high-dose enhancement of adverse effects. Endpoints displaying this curve include carcinogenesis, mutagenesis, and disease incidence

J-shaped dose–responses (Figure 1). The documentation to support the conclusion of the primacy of the hormetic model is widely published and substantial [6, 7]. The hormetic dose–response has been demonstrated to be highly generalizable across biological models (e.g., plant, microbial, invertebrate, vertebrate), endpoints, and chemical classes. Using *a priori* entry and evaluative criteria, the hormetic model has also been found to be far more common than the revered threshold model in multiple head-to-head comparisons [1–3] involving data from toxicological and pharmaceutical studies. Using rigorous *a priori* entry and evaluative criteria, these investigations indicated the hormetic dose–response occurred unequivocally in approximately 40% of the dose–responses. When directly compared with the threshold model, hormesis was found to be 2.5 times more common than dose–responses satisfying the threshold model.

Historical Blunders

Given these substantial findings, the question is how could the entire fields of pharmacology, toxicology, other life science disciplines, and risk assessment make an error on the most fundamental concept upon which their disciplines were built, that is, the dose–response. The critical mistake, which involved concluding that the threshold model was the most fundamental dose–response model, grew out of a long, hostile and economically driven dispute between what is now called *traditional medicine* and the medical practice of homeopathy. At the center of the dose–response controversy was Hugo Schulz, a physician and academic pharmacologist at the University of Grieswald in northern Germany, who reported that low doses of numerous disinfectants reliably caused a low-dose stimulation and a high-dose inhibition of yeast metabolism, that is, the hormetic dose–response [8, 9]. Schulz quickly came to believe that these findings provided the explanatory principle of homeopathy, a belief based on earlier research with homeopathic medicinal preparations that seemed to effectively cure patients with gastroenteritis, yet did so without killing the causative bacteria [10]. Schulz hypothesized that this homeopathic medicine, and others in homeopaths’ arsenal of treatments, may enhance the adaptive capacity of ill individuals, thereby affecting disease resistance.

Data demonstrating low-dose stimulatory responses within yeasts led him to believe this hypothesis was validated. While Schulz became widely known within the homeopathic field, he and his work became the object of considerable attacks and ridicule by leaders in the field of traditional medicine, especially those with high visibility in the field of experimental pharmacology [11–13]. The criticism of Schulz was more political than scientific as Clark tried to associate Schulz with extremist (i.e., high dilutionist) positions within homeopathy. The work of Schulz was disparaged in the leading pharmacological textbooks and the nascent hormetic dose–response concept (i.e., then called the *Arndt–Schulz law*, later to be named *hormesis* in 1943 by forestry researchers at the University of Idaho based on the Greek word *to excite*) [14] became largely excluded from the mainstream of biomedical research [15]. In addition to trying to prevent the theories of Schulz from gaining acceptance, Clark and colleagues promoted the use of the threshold model and its widespread application, including numerous publications by Bliss [16, 17] that were targeted to different biological subdisciplines (e.g., microbiology, entomology, food sciences, etc.). In addition, colleagues of Clark also developed the probit model for dose–response modeling and constrained low-dose modeling to asymptotically approach the origin, denying it the flexibility to model J-shaped dose–responses [18, 19]. This had the effect of negating the possible biological reality of hormetic effects, suggesting that such responses were background variation. These constraining biostatistical approaches became integrated into toxicology, adopted by regulatory agencies and are still used to guide low-dose risk assessment modeling for carcinogens. This perspective was easily viewed as correct since the hormetic dose–response was hard to prove because of the modest nature of the low-dose stimulatory response (see discussion below). This being the case, it was easier to simply consider such responses as background variability and not to test such below-threshold response hypotheses in a rigorous fashion, since it would require more doses, larger number of subjects for improved statistical power calculations along with the greater need for study replication. For a number of reasons, therefore, the hormetic model was marginalized while the threshold dose–response model became relied upon and promoted.

Resurgence of Hormesis

Despite numerous obstacles, the hormesis concept has witnessed a major resurgence in interest during the past decade. This “rediscovery” of the hormesis concept was ironically stimulated by regulatory agencies such as the US EPA that had implemented highly conservative linearity at low-dose modeling into risk assessment practices for carcinogens. This practice resulted in such prohibitively expensive exposure standards and clean-up activities that alternative dose–response models were sought to challenge these regulatory activities by major private-sector entities. It was within that context that hormesis generated much interest; it was suggested that carcinogens would display not only a dose–response threshold thereby challenging the linearity concept, but that doses below the threshold may reduce risks below background (i.e., display hormesis). In fact, substantial studies dealing with chemical carcinogens [20] and radiation [21] have reported J-shaped hormetic dose–responses for cancer endpoints. For example, the ED01 study, the largest cancer bioassay ever conducted with rodents, indicated a clear J-shaped dose–response for the genotoxic carcinogen, 2-acetoaminofluene (2-AAF) induced bladder cancer [5] (Figure 2). Very reliable J-shaped dose–responses have also been reported for several liver carcinogens, such as DDT (Figure 3) [22] along with considerable mechanistic follow-up research.

While many toxicologists now acknowledge the existence and reproducibility of hormetic dose–responses, there is the demand to better understand the underlying mechanisms to account for hormetic dose–responses. In fact, numerous cases of specific mechanisms have been clarified, and reliably account for the biphasic nature of the dose–response in several dozen receptor-based systems (Table 1) affecting a broad range of tissues and endpoints from numerous animal models.

Despite the broad diversity of hormetic-biphasic dose–responses along with the uniqueness of the tissue specific receptor-based mechanisms, the quantitative features of this vast array of dose–response relationships are remarkably similar with respect to the amplitude and width of the stimulatory response (Figure 4). The magnitude of the hormetic dose–response is characteristically modest, with the maximum stimulation usually only 30–60% greater than

Figure 2 Effect of DDT on number of GST P-positive foci in F344 rat livers in two bioassays assessing different but slightly overlapping doses of carcinogen. Note: as the dose decreases the J-shaped dose-response becomes evident. Also note difference in scale between the two graphs [Reproduced from [23]. © John Wiley & Sons, Inc., 2002.]

Table 1 A partial listing of receptor systems displaying biphasic dose–response relationships

Adenosine	Neuropeptides
Adrenoceptor	Nitric oxide
Bradykinin	NMDA
CCK	Opioid
Corticosterone	Platelet-derived growth factor
Dopamine	Prolactin
Endothelin	Prostaglandin
Epidermal growth factor	Somatostatin
Estrogen	Spermine
5-HT (serotonin)	Testosterone
Human chorionic gonadotrophin	Transforming growth factor β
Muscarinic	Tumor necrosis factor α

control values. This is the case regardless of toxic potency as well as with respect to normal and high-risk segments of the population [24]. That is, that individuals displaying greater susceptibility to toxic agents display the same quantitative features of the dose–response as the more resistant members of the population. The width of the stimulatory response is typically within a range of approximately 1/5–1/20th of the toxic threshold as estimated by the no observed adverse effect level (NOAEL) or the zero equivalent point (ZEP). In a small minority (i.e., 2%) of the hormetic dose–responses, the width of the stimulatory responses has been reported to exceed a factor of 1000 [2]. The reasons for

this wider stimulatory zone is unknown, but may be related, at least in part, to population sample heterogeneity.

Hormesis in Perspective

Of particular importance is that the hormetic dose–response is a basic component to the traditional toxicological dose–response, with the hormetic response being immediately below and contiguous with the toxic threshold. This is of considerable value since it permits researchers and risk assessors to place the hormetic response within a dosage zone that can be tested and either validated or disproven, a feature that linearity at low-dose modeling cannot offer; the hormesis response can also be placed within a risk assessment framework that can be integrated into biostatistical modeling as well as fit into uncertainty factor evaluation for application in noncarcinogen risk assessment. This generalized dose–response feature of hormesis, independent of endpoint, has important implications as a feature that can facilitate the harmonization of carcinogen and noncarcinogen risk assessment methods, a long-standing issue for current risk assessment practices. Consequently, it is expected that the hormetic dose–response will have a progressively more influential role in toxicology and risk assessment. This is especially the case, as low-dose concerns become even more significant to society.

Hotspot Geoinformatics

Introduction and Background

Quantitative environmental and *ecological risk assessment* (see **Ecological Risk Assessment**) has been a relatively new and rapidly developing area during the past quarter century. Numerous important issues have been discussed in the two recent NAS/NRC reports entitled *science and judgment in risk assessment*, and *issues in risk assessment*. On the methodological side, a special issue of the international journal, *Environmental and Ecological Statistics*, is devoted to statistical issues and approaches to some current topics in environmental risk assessment [1].

We now live in the age of geospatial technologies. The age-old geographic issues of societal importance are now thinkable and analyzable. The geography of disease is now just as doable as genetics of disease, for example (see **Spatial Risk Assessment; Spatiotemporal Risk Analysis**), and it is possible to pursue it in an intelligent manner with the availability of the rapidly advancing geospatial information technology.

Government agencies continue to require meaningful summaries of georeferenced data to support policies and decisions involving risk maps, geographic targets, and resource allocations. So also the public with initiatives of digital governance, enabling transparency, efficiency, and efficacy in the risk assessment and management.

This article briefly introduces hotspot geoinformatics for hotspot detection and prioritization, and provides examples of societal importance involving environmental risk.

Ecological Diversity as a Motivating Example

Quantification for Ecological Diversity

Conservation biology, landscape ecology, and ecosystem-oriented natural resources management lend considerable urgency to issues and approaches concerning biodiversity assessment. Most of the traditional approaches and statistical tools are plot-based

with a goal of definitive characterization. Diversity, however, is relative to a spatial scale, temporal scale, and taxocene spectrum. Patterns may be more informative than absolutes in this regard.

The issues are fundamental in that, explaining the effects of environment on the distribution and abundance of species is the essence of much ecological work. The controversies arise from the intrinsic scientific importance of diversity theories, as well as from the broad economic and social ramifications of considering biodiversity in land use decisions. At the heart of the scientific and social controversies regarding diversity are problems of quantification, interpretation, and analysis.

The classical view of diversity remains important for intensive studies of particular ecological communities and forest stands [2]. However, the emerging sciences of landscape ecology and conservation biology have made evident the logistical and economical impracticality of such intensive observational coverage for regions in the order of square kilometers and larger [3]. These spatial scales are necessarily encompassed by contemporary ecosystem-oriented resource management and design of regional/national networks of biodiversity reserves. Furthermore, species/area and minimum viable population issues become fundamental in these matters.

The multidimensional character of diversity can be revealed by establishing an intrinsic, and index free, diversity ordering. In effect, diversity may appear to have decreased when viewed from one vantage point (i.e., index), and increased when viewed from a different perspective.

In view of the inadequacy of a single index, Patil and Taillie [4, 5] quantify diversity by means of diversity profiles. A diversity profile is a curve depicting the simultaneous values of a large collection of diversity indices. Thus, the profile portrays the views of diversity from many different vantage points simultaneously and in a single picture.

Differences in community diversity are studied by comparing profiles. If the two communities are intrinsically comparable, then one profile will lie uniformly above the other. Conversely, when the communities are not intrinsically comparable, their profiles may intersect. But even here, the profiles can reveal which portions of the community have undergone opposing diversity changes.

Indicators for Ecological Diversity

We proceed to consider ways of coping with complexity and confounding that embrace multiple indicators rather than agonizing over choices and conflicts of diversity measures. We contemplate enlarging the orders of indicators to encompass some interactions in a formal manner that accommodates both parameterization and visualization. We conclude by noting the convergence of biodiversity and ecological community concepts at meter scales, but not for broader landscape, regional, and global scales of ecological organization.

The indefiniteness regarding biodiversity that can give rise to frustration is well expressed by Taylor [6] in the following quote:

Diversity so pervades every aspect of biology that each author may safely interpret the word as he wishes and there is consequently no central theme to the subject. We cannot be sure if this flexibility is healthy or due to lack of discipline, but it can be traced back to the beginnings of interest in biological diversity ...

The recent programs of the US National Science Foundation probing biocomplexity in many contexts serve to provide evidence that the flexibility addressed by Taylor is both healthy and indicative of need for strengthening discipline with regard to scientific constructs and means by which they are made operational.

Indicators/expressions of this nature are appropriate, and therefore of value, if they convey the desired information within the budget and delivery delays that are acceptable. One method is more efficient than another if it conveys the required information either more rapidly or at less cost. Conveying more information at the same cost and timing is not necessarily desirable if unwanted information has to be processed or filtered.

Increasingly sophisticated management, intervention, remediation, and regulation require a continuing flow of multiple indicators for various aspects of ecosystems.

What ecosystem managers and regulators seek is a complementary set of indicators that captures aspects of interest. We have thus entered the exciting age of indicators; for ecological diversity and biodiversity.

And so also for environmental risk exactly in a similar manner.

Hotspot Geoinformatics of Detection and Prioritization

In geospatial and spatiotemporal surveillance, it is important to determine whether any variation observed may reasonably be due to chance or not. This can be done using tests for spatial randomness, adjusting for the uneven geographical population density as well as for age and other known risk factors. One such test is the spatial scan statistic, which is used for the detection and evaluation of local clusters or hotspot areas. This method is now in common use by various governmental health agencies, including the National Institutes of Health, the Centers for Disease Control and Prevention, and the state health departments in New York, Connecticut, Texas, Washington, Maryland, California, and New Jersey. Other test statistics are more global in nature, evaluating whether there is clustering in general throughout the map, without pinpointing the specific location of high or low incidence or mortality areas.

Scan Statistic Approach for Geospatial Hotspot Detection

Three central problems arise in geographical surveillance for a spatially distributed response variable indicator, generating a cell-wise constant cellular surface (see Figure 1). These are (a) identification of areas having exceptionally high (or low) response, (b) determination of whether the elevated response can be attributed to chance variation (false alarm) or is statistically significant, and (c) assessment of explanatory factors that may account for the elevated response. The circle-based spatial scan statistic

Figure 1 Cellular surface

[7, 8] has become a popular method for detection and evaluation of disease clusters. In space–time, the scan statistic can provide early warning of disease outbreaks and can monitor their spatial spread. The response variable/indicator in this case is disease rate in the case–control situation for binomial distribution and in the case count situation for Poisson distribution.

ULS Scan Statistic. A new version of the spatial scan statistic is designed for detection of hotspots of arbitrary shapes and for data defined either on a tessellation or a network. This version looks for hotspots from among all connected components of upper level sets (ULSs) of the response rate and is therefore called the *upper level set* scan statistic [9]. The method is adaptive with respect to hotspot shape since candidate hotspots have their shapes determined by the data rather than by some *a priori* prescription like circles or ellipses.

Continuous Response Situations. The circle-based scan statistic methodology can be extended to include continuous response distributions, such as, three parametric families of distributions: gamma distribution, lognormal distribution, and scaled beta distribution. The first two families apply to responses that can range from zero to infinity, while the third is for bounded responses. The overall approach is to model the mean and relative variance in terms of the size variable. These moments are functions of the parameters of the response distribution, so that a likelihood function can be written down and parameters estimated by maximum likelihood.

Our strategy for handling continuous responses is thus to model the mean and variance of each cellular response distribution in terms of the size variable Aa for cell a ; modeling is guided by the principle that the mean response should be proportional to Aa and the relative variability should decrease with Aa . Just as with the Poisson and binomial models, we take the Ya to be independent. The approach is best illustrated for the gamma family of distributions, as follows:

We parameterize the gamma distribution by (k, β) , where k is the index parameter and β is the scale parameter. Thus, if Y is a gamma distributed variate,

$$E[Y] = k\beta \text{ and } \text{Var}[Y] = k\beta^2 \quad (1)$$

Both k and β can vary from cell to cell but additivity with respect to the index parameter suggests that we take k proportional to the size variable:

$$ka = \frac{Aa}{c} \quad (2)$$

where c is an unknown parameter but whose value is the same for all a . This gives the following mean and squared coefficient of variation:

$$E[Ya] = \beta Aa/c \text{ and } \text{CV}^2[Ya] = c/Aa \quad (3)$$

Multivariate Hotspotting. When we have multiple indicators representing multidimensional landscape level cellular environmental risk, multivariate hotspotting has been conceptualized [10].

Hotspot Prioritization with Multicriteria Indicators

At times, several hotspots are discovered and in response to several stakeholders resulting in their criteria, scores, and/or indicators, the hotspots need to be prioritized and ranked without crunching the indicators into an index. This gives rise to a data matrix of rows for hotspots and columns for indicator scores. And the problem becomes a partial order theory problem and has been addressed in [11]. Broadly speaking, this paper is concerned with the question of ranking a finite collection of objects when a suite of indicator values is available for each member of the collection. The objects can be represented as a cloud of points in indicator space, but the different indicators (coordinate axes) typically convey different comparative messages and there is no unique way to rank the objects while taking all indicators into account. A conventional solution is to assign a composite numerical score to each object by combining the indicator information in some fashion. Consciously or otherwise, every such composite involves judgments (often arbitrary or controversial) about trade-offs or substitutability among indicators.

Rather than trying to combine indicators, we take the view that the relative positions in indicator space determine only a partial ordering and that a given pair of objects may not be inherently comparable. Working with Hasse diagrams of the partial order, we study the collection of all rankings that are compatible with the partial order (linear extensions).

Figure 2 Hasse diagram of poset A (a) and a decision tree enumerating all possible linear extensions of the poset (b). Every downward path through the decision tree determines a linear extension. Dashed links in the decision tree are not implied by the partial order and are called *jumps*. If one tried to trace the linear extension in the original Hasse diagram, a “jump” would be required at each dashed link. Note that there is a pure-jump linear extension (path a, b, c, d, e, f) in which every link is a jump

See Figure 2. In this way, an interval of possible ranks is assigned to each object. The intervals can be very wide, however. Noting that ranks near the ends of each interval are usually infrequent under linear extensions, a probability distribution is obtained over the interval of possible ranks. This distribution, called the *rank-frequency distribution*, turns out to be unimodal (in fact, log-concave) and represents the degree of ambiguity involved in attempting to assign a rank to the corresponding object. See Table 1.

Stochastic ordering of probability distributions imposes a partial order on the collection of rank-frequency distributions. This collection of distributions is in one-to-one correspondence with the original collection of objects and the induced ordering

on these objects is called the *cumulative rank-frequency (CRF) ordering*; it extends the original partial order. See Figure 3. Although the CRF ordering need not be linear, it can be iterated to yield a fixed point of the CRF operator. We hypothesize that the fixed points of the CRF operator are exactly the linear orderings. The CRF operator treats each linear extension as an equal “voter” in determining the CRF ranking. It is possible to generalize to a weighted CRF operator by giving linear extensions differential weights either on mathematical grounds (e.g., number of jumps) or empirical grounds (e.g., indicator concordance). Explicit enumeration of all possible linear extensions is computationally impractical unless the number of objects is quite small. In such cases, the rank-frequencies can be estimated using discrete Markov chain Monte Carlo (MCMC) methods (see **Bayesian Statistics in Quantitative Risk Assessment**).

Some Examples

Drinking Water Quality and Water Utility Vulnerability

New York City has installed 892 drinking water sampling stations across the five boroughs. Each 4.5-ft high station is located outdoors and draws water from a nearby water main (see Figure 4). The purpose is to monitor general water quality, detect potential health threats, and thwart bioterror activity. Sampling frequency was increased after the 9/11 attacks and, currently, about 47 000 water samples are analyzed annually. Parameters analyzed include: bacteria, chlorine, pH, inorganic and organic pollutants, color, turbidity, odor, and many others. The

Table 1 Rank-frequency table for the poset of Figure 2. Each row gives the rank-frequency distribution for the corresponding element of the poset

Element	Rank						Totals
	1	2	3	4	5	6	
a	9	5	2	0	0	0	16
b	7	5	3	1	0	0	16
c	0	4	6	6	0	0	16
d	0	2	4	6	4	0	16
e	0	0	1	3	6	6	16
f	0	0	0	0	6	10	16
Totals	16	16	16	16	16	16	

network version of the ULS scan statistic can provide a real-time surveillance system for detecting and evaluating water quality hotspots within the distribution system on a parameter-by-parameter basis.

An overall assessment of water quality at each sampling station taking all parameters into account is achieved by employing recent progress on multi-criterion ranking using poset (partially ordered set) prioritization [11] (see **Water Pollution Risk**).

New York City Subway System Syndromic Surveillance

For certain problems, there is an underlying network structure on which we will want to perform the

cluster detection and evaluation. For example, the New York City Department of Health (DOH) is monitoring the New York subway system and water distribution networks for bioterrorism attacks. In such a scenario, a circular scan statistic is not useful as two individuals close to each other in Euclidian distance may be very far from each other along the network. However, the ULS methods will be employed for the detection and evaluation of clusters on a predefined network. The essentially linear structure of these networks, compared with tessellation-derived networks, is expected to have a major impact on the form of the null distributions and their parametric approximations.

The DOH and Metropolitan Transportation Authority (MTA) began monitoring subway worker absenteeism in October 2001 as one of several surveillance systems for the early detection of disease outbreaks. Each day the MTA transmits an electronic line list of workers absent the previous day, including work location and reason for absence. DOH epidemiologists currently monitor temporal trends in absences in key syndrome categories (e.g., fever-flu or gastrointestinal illness). Analytic techniques are needed for detecting hotspots within the subway network.

Choice of Indicator Class for Watershed Biological Impairment

There has been considerable work on determining a suitable method to accomplish a satisfactory ordering of a group of objects, when there are multiple evaluation criteria. Data from 21 watersheds of the Atlantic slope consortium (ASC) has been examined with the goal of determining an accurate ranking by overall watershed condition. In particular, there are three levels of indicators that range from Level I to Level III, increasing in the quality and accuracy of the data as well as the cost and effort needed to obtain the data. Due to the high cost, Level III data is available only for six watersheds; however, the interest is in ranking all 21 watersheds [12]. We use elements of poset (partial order set) theory as a foundation for our analysis. The poset linear extension method can be used to find rankings without using an index, relying only on pairwise comparisons of the objects.

The data relates to a set of 21 watersheds from the ASC, which has the goal for determining an accurate ranking of the health of the watersheds [13] (see

Figure 5 The 21 watersheds from the mid-Atlantic area

Figure 5). There are 15 indicators each of which measures a facet of the watershed and are grouped into Level I to Level III, increasing in quality and accuracy as well as amount of cost and effort. For all 21 watersheds, we have data for seven Level II indicators, and for five Level I indicators. The data matrix for Level II indicators has 21 rows and 7 columns, and the data matrix for the Level I indicators has 21 rows and 5 columns. For Level I and II, the data was scored between 0 and 1. The three levels are as follows:

- Level III – intensive field assessment
- Level II – rapid field assessment
- Level I – landscape assessment from geographic information systems (GISs).

The indicators are categorized by the level of accessibility and availability. Level III, intensive field assessment, is the most expensive among the three levels. We consider the indicators of Level III, the best quality of data we have regarding the watershed. Due to the money and effort in the procedure of obtaining this data, it is available only for six watersheds.

The three Level III indicators are collected from the Index of Biological Integrity (IBI) developed by the Environmental Protection Agency (EPA). They are benthic IBI, fish IBI, and NO_3 . The two IBI indicators are biological indicators, while the NO_3 is considered a chemical indicator.

The Level II rapid field assessment is obtained from on-site sampling. A certain level of expertise is involved in the field assessment. Generally, Level II data is relatively cheap compared to the Level III data. The Level I landscape assessment is the satellite data, and is the easiest to access and the least expensive. The poset prioritization and ranking analysis of the data recommends use of Level II or even Level I indicators to estimate the true ranking of the 21 watersheds by their biological condition.

More Examples and Applications

Geospatial and spatiotemporal environmental risk mapping commands vast literature. Some publications concentrate on geospatial cellular modeling of environmental risk, the probability of adverse event, and thus providing a cellular surface. Some provide

discrete or continuous profiles, allowing extraction of indicators, whereas still others, attempt to identify and provide surrogate indicators for the environmental risk. Applications abound. See, for example, publications and/or websites for:

1. Regional Vulnerability Assessment Indicators of the USEPA ReVA program.
2. Indicators of Ecological Value, Ecological Sensitivity, and Anthropogenic Pressure of the Map of Italian Nature Program.
3. Tsunami Inundation Risk Mapping and Management Program of NOAA.
4. Environmental Risks and Surrogate Indicators around the World for Forest Fires, Pests, Insects and Diseases, Infectious Disease Vectors, Floods, Landslides, Droughts, and others.
5. The Next Generation of Ecological Indicators of Wetland Condition, EcoHealth, the Journal.
6. Ecological Indicators, the Journal.
7. For several environmental and ecological landscape level indicators and related analyses, see Johnson and Patil [14] and Myers and Patil [15].

Future Directions

Surveillance geoinformatics of hotspot detection and prioritization for environmental risk is a critical need of the twenty-first century. Next generation decision support system within this context is crucial. It will be productive to build on the present effort in the directions of prototype and user-friendly methods, tools, and software, and also in the directions of thematic groups, working groups, and case studies important at various scales and levels. The authors have such a continuation effort in progress within the context of digital governance with the National Science Foundation (NSF) support and would welcome interested readers to join this collaborative initiative.

Human Reliability Assessment

Overview of Human Reliability Assessment

Human reliability assessment (HRA) is concerned with predicting the impacts of human performance and error on risk. HRA is a hybrid discipline, belonging simultaneously to the fields of risk assessment and reliability engineering, as well as human factors and ergonomics (the study of humans in work environments). It seeks to deal with the difficult issue of human error, which can cause or contribute to accidents, but also with human error recovery, which can save lives and prevent or reduce system losses. The human operator (a generic term used throughout this chapter) is the key ingredient in many industries and work systems, including nuclear power plants, chemical and oil and gas installations, aviation and air traffic management systems, rail networks, space missions, military systems, and hospitals. These are all areas where HRA is currently in use or being developed to help avoid accidents leading to fatalities and unacceptable system losses.

HRA usually fits into a risk (or reliability) assessment, which is concerned with how a system can fail and/or lead to accidents involving loss of life or resources. Risk assessment asks several questions:

- What is the scope of the system under investigation?
- What can go wrong?
- How likely is it to go wrong?
- What will be the consequences?
- Is the risk (the product of the undesirable event's likelihood and consequences) acceptable?
- Can risk be reduced?

Figure 1 depicts the main stages of risk or safety assessment [1]. HRA's role in risk assessment is to evaluate the human contribution to risk, which can be positive or negative. HRA's functions therefore reflect those of risk analysis. In particular, HRA usually attempts to answer the following questions:

- What is the human involvement in the system?
- What can go wrong?

- How likely is it to happen?
- What can be done to reduce error impact?

The first question is usually answered by the application of *task analysis* (see **Systems Reliability**) [2], which defines the human being's tasks, procedures to be followed, equipment required, etc. For example, an air traffic controller might give the pilot of an aircraft an instruction to climb to a particular flight level, using a radiotelephone. The task would be "give instruction to pilot". The second question is served by *human error analysis* (see **Reliability Data; Probabilistic Risk Assessment**), a range of techniques that aim to identify human errors that could cause or contribute to system failure or degradation. A typical example is that the pilot mishears the flight level given by the controller, and climbs to a higher level, one which is perhaps already occupied by another aircraft. Such an error obviously can introduce a risk into the system, namely the risk of a midair collision. The third question is answered by using the techniques of *human error quantification*, which estimate how likely such an error is to happen, expressed it as a probability. The *human error probability* (HEP) (see **Behavioral Decision Studies**) is ideally a statistical entity derived from observations or tasks and errors that arise during their execution, e.g.:

$$HEP = \frac{\text{number of errors observed}}{\text{number of opportunities for error}} \quad (1)$$

In this example, on the basis of research into this type of error, it may be expected to occur approximately three times in a 1000 opportunities (instructions). This sounds reasonably low, but of course there are many thousands of flights each day. To compensate for this, there are a number of recovery and mitigation factors built into the system that the risk assessment can take account of.

First, the copilot in the aircraft may detect the error, since he or she will overhear the controller-pilot interaction. Second, the pilot should "read back" the flight level to the controller, who can therefore detect the "mishearing". Third, the controller is watching the aircraft on a radar screen, and may realize it is climbing beyond its "cleared" level. Fourth, there is an alarm to warn the controller if two aircraft get too close, and also (fifth) a completely independent alarm aboard the aircraft to alert the pilots and to tell them how to avoid the other aircraft. Sixth, the other aircraft will be listening on the same

Figure 1 A generalized seven-stage safety assessment process

frequency and may hear the instruction, whereupon the pilot of that aircraft will contact the controller immediately. Last, there is sufficient space in the skies that chances of midair collision are still rare even if all these system factors fail to prevent the error propagating toward disaster. The human error rate may therefore be deemed tolerable, because its effects can be absorbed by other system defenses. Alternatives such as full automation may seem like a solution, but experience shows that automation can introduce its own problems, in particular a lack of recovery when it goes wrong, something that would be unacceptable when considering mass public transportation by air, for example.

This example at first sight suggests that human reliability is quite good (e.g., 3 errors in a 1000 opportunities is not so bad), but then when the sheer number of flights and controller–pilot interactions are considered, it appears problematic. In fact, upon detailed risk analysis, there are many recovery layers in the system, so risk is acceptable. But for the midterm future (e.g., 2020), where the number of flights is predicted to double or even triple in line with public demand for more air transportation, it may be necessary to introduce a new layer or defense. This could involve *human error reduction*, e.g., better

training to ensure the copilot or controller hears the error, or a system-based mitigation, such as sending an electronic message from the aircraft’s onboard flight management system to the ground control system, to compare what the controller input into his system with what the pilot input into his (a consistency check), and thereby alarming much earlier than current systems allow if an error occurs.

This example shows that the human reliability for a task needs to be seen in the context of the system to make meaningful decisions about risk. This tends to be true whether considering aviation, nuclear power, rail, space, or medical contexts. Whereas human factors [3] often work independently, HRA therefore mainly occurs within the framework of a risk or reliability assessment [4]. HRA analysts usually work closely with risk analysts, as well as system designers and operational personnel. The HRA analyst’s job may be described as being that of a detective investigating a negative “event”, but where the “event” has not yet occurred.

The HRA Process

A generic HRA process is shown in Table 1 [5], from scoping the problem the HRA is being asked

Table 1 The HRA process

<i>Problem scoping</i>	– Deciding what is in the scope of the assessment – e.g., the principal human interactions and functions; what nonnominal events could occur (including adverse weather and traffic patterns); what failures, whether maintenance activities are included; etc. This “context” is normally set by the safety assessor and HRA/human factors practitioner.
<i>Task analysis</i>	– The detailed analysis of the human contribution in the risk scenario – what the controllers/pilots should do, and with what resources (displays, communication media, etc.).
<i>Error identification</i>	– What can go wrong – from simple errors of omission (e.g., fail to detect wrong readback) to more complex errors of commission (e.g., right instruction given to wrong aircraft).
<i>Representation</i>	– Modeling the human errors and recoveries in the risk model, whether this uses fault and event trees, Petri nets, or some other modeling approach. This puts human errors and recoveries into the larger system context, alongside other system failures and defenses. Representation enables an accurate view of how errors propagate through the system, and whether they will indeed ultimately affect system risk.
<i>Dependence analysis</i>	– Explicit quantitative accounting for dependence between different errors and error conditions.
<i>Screening</i>	– Conservative (pessimistic) error probabilities can be used along with sensitivity analysis to determine which human errors are “risk sensitive” and which will have negligible impact on risk. The former can then be quantified in more depth, and the latter ignored.
<i>Quantification</i>	– Derivation of HEPs for errors using a formal quantification method. Quantification may also develop uncertainty bounds or confidence levels for individual HEPs.
<i>Evaluation</i>	– Determination of the impact of human error on risk, and the most important human contributions to risk, within the risk framework or representation. This usually involves comparison of the total predicted risk against a target level of safety, or else future system’s risk will be contrasted with today’s risk levels, to ensure that the future system will be at least as safe as today’s.
<i>Error reduction</i>	– On the basis of the evaluation and the prior qualitative stages (task analysis, error identification and representation), human factors and/or safety requirements may be specified to reduce the HEP and/or its impact on risk to achieve a more acceptable risk level.
<i>Documentation</i>	– Documentation of the analyses, calculations, assumptions, and recommendations to inform the designers, implementers, and operators/managers, as well as to the appropriate regulatory authority.

to address, through to documentation. Within the confines of this chapter on HRA, only 3 of these 10 steps will be covered: task analysis, error identification, and quantification (with brief treatment of dependence). Most emphasis is placed on the error identification and quantification stages in HRA, the first to try to make the concept of human error clearer and the second because it is most often seen as the quintessential element of HRA. These two steps generally dominate HRA outputs. For a fuller description of all 10 steps, see [5].

The remainder of this chapter outlines the “mechanics” of HRA – what it looks like and how it works, showing examples of actual techniques. It then considers the validity of the central approach, that of human error quantification, and finally discusses contemporary HRA issues including second generation HRA techniques, safety culture, and HRA “ethics”.

How HRA Works

This section gives examples of practical techniques and approaches of task analysis, error identification, and quantification (including dependence aspects) and error reduction. For more general background information on HRA, see [5–8].

Task Analysis

Task analysis (*see Systems Reliability*) [2] is a set of methods for capturing and describing the human operator involvements in a system. The classic form of task analysis is hierarchical task analysis (HTA), an example of which is shown in Figure 2. The figure is read top-down and starts from a goal – in this case “launch lifeboat” from an offshore oil and gas installation during an emergency. This goal is served by five subsidiary tasks which follow a plan

Figure 2 Example HTA for launching a lifeboat

requiring them to be carried out in order, e.g., check boat. This task requires two operations, shown in the diagram simply as “A” and “B” but in fact they are “check maintenance valve is closed” and “release retaining hook”. This simple type of hierarchical decomposition of a task is in fact a good way to define the operator’s role. Task four is decomposed in full detail to show the types of human “operations” that achieve the task “final checks”. This type of task analysis is a useful starting point for a HRA analyst and acts as a blueprint of what the human operator is supposed to do in a system.

Incidentally, this style of task analysis is also used by training departments to determine training needs, as well as by those operational groups that must write formal procedures for operators. Other formats of task analysis [2] can be used to focus on, for example, team interactions under time constraints (using vertical and horizontal timeline analysis), operator interaction with a human machine interface such as a computer screen (tabular task analysis), distributed operations in different locations (link analysis), etc. Task analysis can therefore describe the “nominal case”, i.e., what the operator(s) should do – the rest of HRA then considers what can go wrong and how to increase reliability.

Human Error Identification

Human Error Theory. Once task analysis has been completed, human error identification can then

be applied to consider what can go wrong. Human error has been defined as follows:

Any member of a set of human actions or activities that exceeds some limit of acceptability, i.e., an out-of-tolerance action where the limits of human performance are defined by the system [9].

Such a definition gives rise to the following overt error types that should be considered during any human error analysis:

- Omission error – failing to carry out a required act.
- Action error – failing to carry out a required act adequately:
 - act performed without required precision, or with too much/little force;
 - act performed at the wrong time;
 - act performed in the wrong sequence
- extraneous act – act performed which is not required (also called error of commission, EOC).

This classification tells us neatly what can happen, but gives little indication as to the causes or remedies for such errors. It also fails to capture the notion of different types of behavior and error forms, in terms of different causes and “internal” or cognitive failure mechanisms, and the important notion of intentionality of error, i.e., that some errors are intentional and others are not.

Although HRA is very applied in nature, the analyst must have an understanding of the theory of human error in order to be effective in identifying what can go wrong. Otherwise, error identification will be superficial and risk may be underestimated. To add more depth to the notion of human error, reference is usually made to four error categories [10]:

- *Slip*

Where the wrong control is activated, e.g., an error while dialing a number to make a phone call, or the wrong message is given, e.g., slips of the tongue.

- *Lapses*

Where something is forgotten, a task step missed out – e.g., when making tea, filling the kettle, but forgetting to switch it on.

- *Mistakes*

Where due to a misunderstanding or misconception, the operators do the wrong thing, e.g., in the Three Mile Island nuclear power accident in 1979, operators believed that the reactor pressure vessel had plenty of water, so switched off the emergency supply when it tried to fill the emptying vessel, thus leading to reactor core damage.

- *Violations*

Where the operators know what they are doing is not allowed, but they do it anyway, usually to make the job easier, e.g., stepping over a barrier around an automated assembly line to retrieve something dropped, without stopping the robot arm that is moving rapidly inside the barrier. Reasons for such a violation could include not wishing to lose valuable production time by stopping the process, and the risk of personal harm could be perceived as low.

Slips and lapses are the most predictable error forms, and are usually characterized as being simple errors of quality of performance or as temporary lapses in memory, often due to distraction. In the lifeboat launching example, for example, a slip might concern pressing the wrong button to start the engine (there are several buttons on the console). But this would normally be rectified quickly (since the engine would not start – nothing would happen). A lapse might involve failing to ensure that all the hatches are secure, which could have more serious consequences when the boat enters the water. General good human factors practice can eradicate most of these types of errors, and good design will tend to mean

that operators who commit them usually discover and correct them before they have adverse consequences on the system. This category, however, also includes slips and lapses in maintenance and testing activities, which may lead to *latent failures* (failures whose impact is delayed, and whose occurrence may be difficult to detect prior to an accident sequence). For example, an emergency backup system may be taken off-line for testing and then it may be tested and deemed working in good order, but the maintenance crew may omit the last critical step of placing it back on-line. This means that if it is suddenly needed in an emergency, it will be unavailable. This is why functional testing is recommended after maintenance activities have taken place. Latent failures are important because they can remove barriers to accidents, while letting the operators believe the barriers are perfectly healthy.

Mistakes refer to the case wherein a human operator or team of operators might believe (due to a misconception) that they are acting correctly, and in so doing might cause problems and prevent automatic safety systems from stopping the accident progression. In a recent air transport accident, a controller saw two aircraft on a collision course and instructed one of the aircraft to descend, unaware that the other aircraft had started descending too (in such cases, one should descend, the other should climb). The pilots onboard trusted the controller more than the onboard automatic collision avoidance system that was telling them to climb, with the result that the two aircraft did in fact collide in midair, with total loss of all passengers and crew on both aircraft. Such errors of misconception are obviously highly dangerous for any industry, since they can cause failure of protective systems.

Violations represent a phenomenon that has only recently been considered in risk assessment, most notably in the hazardous industries since the Chernobyl nuclear power plant accident in 1986. Rule violations inevitably involve some element of risk-taking or risk-recognition failure. There are two basic types [11]: the first is the *routine* or *situational* violation, where the violation is seen as being of negligible risk and therefore the violation is seen as “acceptable” or even a necessary pragmatic part of the job. The second is the *extreme* violation, where the risk is largely understood as being real, as is the fact that it is a serious violation, with punitive penalties attached if discovered. The latter types of violation are believed

to be rare in industry. An example of an extreme violation would be falsification of administrative control procedures, e.g., to say that a test had been carried out successfully, when it had not in fact occurred or had yielded a negative result. Such incidents as these are usually due to “production pressure” and may be seen as a way of keeping one’s job or ensuring the success of the company. Note that actual sabotage and terrorist acts are clearly criminal in nature, and are therefore outside the jurisdiction of HRA.

An EOC is one in which the operator does something that is incorrect and also *not required*. Examples are where a valve which should be locked open is found to be locked closed, or a computer-controlled sequence is initiated, or a safety system disabled, when none of these actions are required, and in some cases when there has not even been a task demand associated with the equipment unit. Such errors can arise due to carrying out actions on the wrong components, or can be due to a misconception, or can be due to a risk-recognition failure. An EOC can be due to a mistake or a violation, but even a simple slip could lead to an EOC, e.g., by activating a completely different (but adjacent) control rather than the one intended. EOCs are of increasing concern, for three reasons: firstly they do appear to happen, even if rarely; secondly, they can have a large impact on system risk and thirdly, they are very difficult and/or laborious to identify in the first place. This means that they may therefore be underestimated in terms of their contribution to risk, or may not even be represented in the risk assessment. Their identification and quantification is difficult, however, and is returned to under the discussion of second generation techniques in the latter part of this chapter.

Human Error Identification – Practice. For a review of human error identification techniques, see [12]. This section outlines four straightforward and accessible approaches.

Operational experience review/critical incident technique. For an existing system, the first and most obvious way to identify errors is reviewing what errors have already led to incidents or accidents in the system under investigation. Most mature industries that are safety critical also have formal safety-related event reporting, recording, and analysis systems, so that the organization can learn from incidents and

avoid their repetition or escalation toward more serious accidents. Such accidents usually involve fatalities and all the grievous losses associated with such tragic events. Additionally, large-scale accidents, particularly those which attract media attention (and most do), can also threaten the very survival of the company. However, not all industries have mature human factors causal analysis systems, instead perhaps simply recording an event as “human error” with no further analysis of why it occurred, and hence how to prevent recurrence. But if an organization has a mature “risk management culture”, then it should have formal human error classification as part of its event reporting procedures and processes.

When carrying out an HRA for a system which already exists or has an equivalent referent system, it is very beneficial to interview operators (and also trainers and supervisors, and of course incident investigators) to ask what types of events have happened. The analyst can simply ask if the interviewee (a single person or a group) knows of any human error-related events that have occurred in the existing system. While this is anecdotal, it can usually be corroborated by existing formal incident records, and such interviews often generate a richness of information, particularly about factors that can affect performance and the existing safety culture in the organization. Two important caveats are first that the analyst has to beware of people’s particular biases (we all have them) such as a potential grudge against the company or the fact that “everyone is a hero in their own story”, and second the analyst must avoid “leading the witness” or putting words into their mouths, based on the analyst’s own values and preconceptions.

At the least, reviewing incident and operational experience ensures that the analyst will be able to identify credible errors that have already happened and will gain a fuller understanding of the factors that affect human reliability in the system’s operational culture.

TRACER. In the early years of applied HRA (the early 1980s), errors were initially identified by risk assessors without any special techniques or processes. This changed by the introduction of structured approaches for error identification, an early example being the systematic human error reduction and prediction approach (SHERPA) [13], which used a series of flowcharts and questions to help the risk

or HRA analyst consider which errors could affect the system under investigation. A common approach used today is TRACER (technique for the retrospective analysis of cognitive errors) [14] which is publicly available. It is a descendant of SHERPA as well as other techniques, and uses a series of taxonomies and flowcharts to identify error possibilities for a system. It also considers error detection and recovery. TRACER is a single-analyst human error identification approach. It was developed to classify the causes of incidents, and then a further version (TRACER Lite) was developed for predictive purposes. It requires first a task analysis, and then applies a series of guide words and other error-related taxonomies to identify both errors and (qualitative) error recovery likelihoods. The framework of TRACER is shown in Figure 3 and one of its main error taxonomies is shown in Table 2.

Note that in Table 2 there is a column called *internal error mechanism*: these guide words are psychological in nature and attempt to describe likely psychological or cognitive mechanisms for the failure.

These may be helpful when later on considering error reduction. As an example, if an action is predicted to be omitted, error reduction will be different if the most likely internal error mechanism was “distraction” as opposed to “insufficient learning”. In the former case, changes to the work environment will need to occur to remove the distractions, whereas in the latter more comprehensive training is likely to be recommended.

Application of TRACER is similar to using failure mode and effects analysis (FMEA) for hardware reliability assessment. The other aspect of TRACER that is noteworthy is that TRACER also considers the likelihood of error recovery.

Human HAZOP. Another approach to identifying errors is called *human hazard and operability study* (HAZOP) [15]. This is a group-based approach which uses a set of guide words of error types applied to a task analysis, with the group comprising a chairperson or group facilitator, a note-taker, a human factors expert, a safety expert, a system designer,

Figure 3 TRACER-Lite overview [Courtesy of Dr. S Shorrock]

Table 2 TRACER-Lite internal error taxonomy (guide words)

Internal error mode	Internal error mechanism
<i>Perception</i>	
Mishear	Expectation
Mis-see	Confusion
No detection (auditory)	Discrimination failure
No detection (visual)	Perceptual overload
	Distraction/preoccupation
<i>Memory</i>	
Forget action	Confusion
Forget information	Memory overload
Misrecall information	Insufficient learning
	Distraction/preoccupation
<i>Decision making</i>	
Misprojection	Misinterpretation
Poor decision or poor plan	Failure to consider side- or long-term effects
Late decision or late plan	Mind set/assumption
No decision or no plan	Knowledge problem
	Decision overload
<i>Action</i>	
Selection error	Variability
Unclear information	Confusion
Incorrect information	Intrusion
	Distraction/preoccupation
	Other slip

and operational experts. Table 3 shows typical guide words used in a human HAZOP. Table 4 then shows an extract of the type of discussion that can occur in a HAZOP, and Table 5 shows an example of how the results are recorded.

HAZOP is a risk and reliability approach and human HAZOP is simply an adaptation to HRA. However, in the few validations (see [16]) that have taken place of error identification techniques, human HAZOP has been shown to be very effective, particularly in identifying credible errors in the areas of violations.

The format in Table 5 can equally be used to represent the outputs from usage of TRACER or SHERPA or other human error identification techniques. It is a useful means of documenting the error's nature and impacts on the system, including barriers that should prevent the error or its effects, and a useful medium with which to identify preliminary error reduction or mitigation measures.

HAZOP has three significant advantages. Firstly, when the safety assessor is trying to identify hazards for a future system, one where there is,

Table 3 Typical human HAZOP guide words*Basic guide words*

- No action

- Maintenance
- Production pressure/risk-taking

Table 4 Excerpt from HAZOP discussion (of electronic strip system design for air traffic controllers)^(a)

HAZOP group member	Discussion
Human factors specialist	If these two objects overlap, could the controller operate on the wrong object, i.e., aiming a message for the one on top but actually communicating with the one that is now flying beneath the top one?
Designer 1	Well, we expect the controller always to move the objects so that they won't overlap, before transmitting a command.
Controller	Well, there might not always be time, but as long as you're operating on the one on top, one coming underneath won't be selected without it being clear, will it?
Designer 1	Hmm. Well, it isn't impossible actually, depending on how long you leave the cursor without entering a command. Presumably that would be no more than a couple of seconds, would it?
Controller 2	Not necessarily, I mean if I'm in the middle of something and then a higher priority call comes in, I'll leave the cursor there and then come back to it. It could be a while, up to a minute.
Designer 2	Right. Okay, we need to take another look at this, and implement some way of highlighting that the original target has been deselected and must be reacquired, otherwise the right message could be sent to the wrong aircraft.
Chairman	So, are we agreed then that we need an action on the designers here to ... ?

as yet, no mature operational concept or procedures, this can be very difficult. There are simply too many open questions to make progress. However, in a HAZOP where experienced operators are present, these experts can usually “fill in the gaps”, interpolating between current practice and future practice of how the system should operate. This means that the preliminary hazards can be identified at a time when the design can still be changed significantly if serious hazards emerge. The second and related advantage is that the composition of the HAZOP group, comprising project design and controller reviewers, often lends itself to promptly identifying design solutions that will increase safety. Once the hazard is identified, the participants will often determine an immediate solution *via* a system change or procedural modification (as in Table 4). The third advantage is that such a process involves the project design and operational personnel in safety discussions. If they really believe a hazard is incredible they will say so, but if not, there is acceptance that such a hazard must be addressed. The approach therefore gains “buy-in” or ownership from the project team. They “own” the results as much as the safety assessors, rather than being given an “external” safety assessment that is seen as a “fait accompli”, which they have to accept only on the basis that they trust that the safety people know what they are doing.

The disadvantages of HAZOP are the resources requirements, since around six experts are needed

to run a HAZOP, and progress can sometimes seem slow. Also, experts may be biased not to identify failures (e.g., if they represent the project or development team). The ideal approach is therefore to utilize an analytic approach like TRACER as well as a human HAZOP approach – this is the most comprehensive formula for identifying all likely errors. If TRACER is carried out first, then its results can be used judiciously to steer the resources of a HAZOP team more effectively, e.g., ignoring already identified “minor” errors with little impact and focusing on the more serious, potential errors and risks of violations, etc.

JHEDI. A final checklist approach is shown in Table 6, from a nuclear power technique known as *justification of human error data information* (JHEDI) [16]. This straightforward technique can be used by a single assessor as a preliminary screening error identification tool.

Once error identification is carried out, there are two paths open to the HRA analyst or risk analyst. The first is where only a quantitative approach is being adopted, i.e., the intent is to examine the vulnerability of the system and seek ways to improve it. In such a case, it is likely that the errors identified (by whatever means) will be ranked or categorized on the order of importance and the assessors will move directly to the step of error reduction or mitigation.

The second path is taken when the HRA is part of a quantitative risk assessment approach. In such

Table 5 Extract of related ATM HAZOP output^(a)

Function	Guide word	Cause	Consequence	Indication	System defenses	Human recovery	Recommendations
Highlight object (aircraft label)	No action	Another item preventing access to target	Difficulty in hooking target aircraft	No highlighting of target	None	Drag blocking object out of way; strategic management of screen items	Design objects to “roll around” each other; use height filtering; flip system to move between object on top and the one beneath; highlight background
Other action	Clustering results in different aircraft being highlighted instead of target		Instruction may be given to wrong aircraft on the system	As above	Highlighting is color coded to indicate direction of travel; call sign is displayed on all menus	As above	As above

Table 6 JHEDI human error analysis questions

-
1. Could a misdiagnosis or misinterpretation occur, possibly due to a misperception of signals, or expectations, the complexity of the situation itself, or a failure to take note of special circumstances?
 2. Could a short-cut or even rule violation occur, due to production pressure or due to a failure to be aware of the hazard?
 3. Could a previous (latent) maintenance or calibration error lead to difficulties or errors in responding to the scenario?
 4. Could a check fail be omitted or occur on the wrong system, or simply be the wrong kind of check?
 5. Could an information–communication error occur?
 6. Could a crew-functioning error occur, such that, for example, it is not clear who is carrying out the task?
 7. Could a required act be omitted because it is at the end of the task, because of a lapse of memory or distraction, or because the operator failed to respond (e.g., due to his or her workload)?
 8. Could the task be carried out in the wrong sequence, or a subtask be repeated, or the operator lose his or her place in the procedures?
 9. Could an action or check be carried out too early or too late?
 10. Could an action be carried out with insufficient precision or force, or just inadequately?
 11. Could an action that is not required be carried out by operating on the wrong object or in the wrong location, or by carrying out an incorrect but more familiar task, or by selecting or acting on the wrong information?
 12. Could any other type of error occur?
-

cases, the human errors will be “represented” in logic trees such as fault and event trees, or in Petri nets if using dynamic risk modeling – these aspects are more properly dealt with in other chapters. But if this pathway is being pursued, the next step requires human error quantification, i.e., determining the probability of human error occurring (where possible together with its uncertainty bounds and probability distributional characteristics). This step in HRA is usually seen as the major part of HRA, and certainly most research over the past 45 years since the birth of HRA has been in this area.

Human Error Quantification

Because human error quantification has been the main part of HRA for over four decades, a brief history of the development is given, before moving on to show how typical techniques work.

Evolution of Human Reliability Assessment.

HRA began in the 1960s at the same time that risk assessment practices were also developing, in the area of missile system development, most notably in various governmental sponsored laboratories (e.g., Sandia National Laboratories) in the United States. For the first two decades, however, HRA was more of a research area than a practical discipline. It “came of age”, however, shortly after the US nuclear power plant Three Mile Island accident happened in

1979. This accident, a partial melting of the nuclear reactor core, was seen as a major demonstration of the vulnerability of systems to human error, so an approach to predict and prevent such errors was urgently required. This led to the first practical HRA technique, the technique for human error rate prediction (THERP) [6], which is still in use today.

THERP. Application of THERP entails carrying out a task analysis of the human involvements in the system, defining human event sequences that need to be carried out to assure safety, and then quantifying these sequences using a database of human error probabilities. THERP uses a database of human error probabilities as its quantification “engine”. This database contains error probabilities for such tasks as reading a display, operating a joystick, responding to an alarm, etc. Some example THERP HEPs are shown in Table 7.

Table 7 shows that human reliability is poor in the first 20 min after the onset of a system abnormality or fault condition. This unreliability is also because nuclear power plants are complex, so some basic diagnosis must take place to determine the fault according to its annunciated symptoms.

THERP recommends consideration of the effects of a large number of factors that can influence human performance (time pressure being one, in the example in Table 7), called *performance shaping factors* (PSF). These factors can range from “external”

Table 7 HEPs for failing to diagnose an annunciated (alarmed) nuclear power abnormal event^(a)

Item	<i>T</i> (minutes after onset)	Median joint HEP for diagnosis of a single, or the first, event	Error factor
1	1	1.0	—
2	10	0.5	5
3	20	0.1	10
4	30	0.01	10
5	60	0.001	10
6	1 day	0.0001	30

^(a) Reproduced from [6]. US Nuclear Regulatory Commission, 1983

factors such as lighting, work hours, and manning parameters, to more “internal” factors such as motivation, experience, and stress. The “error factor” in Table 7 associated with each nominal HEP is then used as a modification factor, e.g., if there was a significant stress on the operators, an HEP might be multiplied by a factor of 10.

THERP was also the first technique (and one of the few) to explicitly consider *dependence*. Dependence is when the success or failure of one action is related to that of a previous action or task. For example, if an operator is calibrating a set of gas detectors and makes a mistake in one because he has the wrong value in mind, then he is likely to miscalibrate all of them. Another example of dependence is when someone is checking another’s work or results – there is usually a certain degree of trust so that the check may not be as thorough as one would hope for. In such cases, adding a third or even fourth “checker” into the equation will not necessarily increase the reliability either, due to a natural dependence.

THERP models dependence in five categories: complete, high, moderate, low, and zero dependence, and modifies the second (dependent) HEP accordingly using a specific formula. The analyst judges dependence according to whether the actions under consideration are being carried out by the same or different people or teams, whether they are using the same equipment in the same location, and whether they are in the same timeframe or not. A useful guide to dependence modeling and countermeasures is given in [17].

Expert judgment methods. Although THERP was immediately successful in the early 1980s, there were

a number of criticisms of the approach, in terms of its granularity of task description and associated human error probabilities. It was seen by some as too “decompositional” in nature. Additionally, its database origins have never been published, and there were concerns from the human factors community about its “broad brush” treatment of psychological and human factors aspects, as well as its significant resource requirements when it came to analyzing a complex system such as a nuclear power plant.

By 1984, there was therefore a swing to a new range of methods based on *expert judgment* (see **Expert Judgment; Experience Feedback; Uncertainty Analysis and Dependence Modeling**). Risk assessment at the time (specifically probabilistic safety assessment or PSA), whose champion was (and still is) the nuclear power industry, was used to applying formal expert judgment techniques to deal with highly unlikely events (e.g., earthquakes and other external events considered in PSAs). These techniques were therefore adapted to HRA. In particular two techniques emerged: *absolute probability judgment* [18], in which experts directly assessed HEPs on a logarithmic scale from 1.0 to 10^{-6} ; and the *success likelihood index method* (SLIM) [19]. The main difference with this technique was that it allowed detailed consideration of PSF in the HEP calculation process. Typical PSFs used by a number of HRA techniques are the following:

- unfamiliarity of the task (to the human operator),
- time pressure or stress,
- training adequacy,
- procedures adequacy,
- adequacy of the human machine interface,
- task complexity.

Expert judgment approaches are useful for considering difficult quantification assignments, for which perhaps there are no clear data available, or where stakeholders themselves want to be sure that the numbers are judged realistic by operational experts. In this sense, expert judgment techniques have some of the advantages of HAZOPs, since they elicit ownership and involvement from the participants, as well as maximizing expertise input by having operational experts involved. Conversely, if the operational experts are not very experienced themselves (a recommended minimum operational experience level is 10 years, and to still be an active operator) or if the system being assessed is way outside their own experience range, then there is the danger of gaining results that are not accurate or are invalid. There is also the danger of biases affecting the judgment process, whether these are memory-based (e.g., giving disproportionate weight to a rare event and ignoring other more representative ones), motivational (e.g., wanting to see a new system built, so underestimating the HEPs), or cognitive (e.g., finding it hard to deal with very low probabilities such as 1 error in 100 000).

HEART, NARA, and SPAR-H. One further technique worthy of note developed in the mid-1980s was the human error assessment and reduction technique (HEART) [20]. This technique had a much smaller and more generic database of HEPs than THERP, which made it more flexible and quicker to use, and had PSF called *error producing conditions* (EPCs), each of which had a maximum effect (e.g., from a factor of 19 to a factor of 1.2) on the HEPs. HEART was based on a review of the human performance literature (field studies and experiments), so the relative strengths of the different factors that can affect human performance had some credibility with the human factors and reliability engineering domains. HEART is still in use today in a number of industries as it is very resource efficient, and has recently been redeveloped as a specific nuclear power plant HRA technique called *nuclear action reliability assessment* (NARA) [21]. As an example of how these techniques work, Tables 8 and 9 show the generic task types (GTTs) for NARA and the EPCs.

The HRA analyst assessing a nuclear power plant therefore, having identified a critical human action, e.g., responding to an alarm, must use Table 8 to pick the appropriate (best fit) GTT. Assuming it is

not a complex pattern, C1 would be selected, with a “nominal” HEP of 0.0004 or 4 errors per 10 000 opportunities (incidentally, this particular GTT is based on observed error rates with experienced UK nuclear power plant operators). The assessor must then (on the basis of prior task analysis and interviews with existing operators or prospective ones if the system is not yet built) consider if there are any human factors that could increase the likelihood of human error. As with most HRA techniques, NARA preidentifies the human factors that are most important for HRA consideration, along with “weighting factors” to determine how large the impact on the HEP will be.

Let us assume that in this case the assessor finds that the human machine interface for displaying alarms is not as good as it should be, and that the alarm condition is rare and will be relatively unfamiliar to the operator. The assessor would then select EPCs 2 (unfamiliarity) and 11 (poor or ill-matched system feedback), with maximum effects on the HEP of 20 and 4, respectively. The assessor then has to make a judgment on how unfamiliar the condition is and how poor the interface is, and this requires assessor training and experience with the technique itself (in NARA descriptive “anchor points” for each EPC also assist the assessor). Let us suppose that the assessor decides in each case to use half of the maximum effect. This is called (in HEART as well as NARA) the *assessed proportion of affect* or *APOA*. The values chosen are then substituted into the following generic NARA quantification equation:

$$HEP = GTT \times \{[(EPC_1 - 1) \times APOA_1 + 1] \times \dots \times [(EPC_n - 1) \times APOA_n + 1]\} \quad (2)$$

Inputting the chosen GTT and EPC information gives the following result:

$$\begin{aligned} HEP &= 0.0004 \times \{[(20 - 1) \times 0.5 + 1] \\ &\quad \times [(4 - 1) \times 0.5 + 1]\} \\ &= 0.0004 \times [9.5 + 1] \times [1.5 + 1] \\ &= 0.0105 \quad \text{or} \quad 0.011 \end{aligned} \quad (3)$$

Thus the final HEP is approximately 1 in 100 opportunities or system demands. This value would then be put into the appropriate fault or event tree. NARA also assesses dependence, using a version of the original THERP dependence model. The form

Table 8 NARA generic task type HEPs

NARA GTT ID	NARA GTT description	NARA GTT HEP
<i>A : Task execution</i>		
A1	Carry out simple single manual action with feedback. Skill based and therefore not necessarily with procedure.	0.005
A2	Start or reconfigure a system from the main control room following procedures, with feedback.	0.001
A3	Start or reconfigure a system from a local control panel following procedures, with feedback.	0.002
A4	Judgment needed for appropriate procedure to be followed, based on interpretation of alarms/indications and situation covered by training at appropriate intervals.	0.006
<i>B : Ensuring correct plant status and availability of plant resources</i>		
B1	Routine check of plant status.	0.02
B2	Restore a single train of a system to correct operational status after test following procedures.	0.004
B3	Set system status as part of routine operations using strict administratively controlled procedures.	0.0007
B4	Calibrate plant equipment using procedures, e.g., adjust set-point.	0.003
B5	Carry out analysis.	0.03
<i>C : Alarm/indication response</i>		
C1	Simple response to a key alarm within a range of alarms/indications providing clear indication of situation (simple diagnosis required). Response might be direct execution of simple actions or initiating other actions separately assessed.	0.0004
C2	Identification of situation requiring interpretation of complex pattern of alarms/indications. (Note that the response component should be evaluated as a separate GTT.)	0.2
<i>D : Communication</i>		
D1	Verbal communication of safety critical data.	0.006

Table 9 NARA error producing conditions

NARA EPC	NARA error producing condition (EPC) description	NARA EPC maximum effect
1	A need to unlearn a technique and apply one which requires the application of an opposing philosophy.	24
2	Unfamiliarity, i.e., a potentially important situation which only occurs infrequently or is novel.	20
3	Time pressure.	11
4	Low signal to noise ratio.	10
5	Difficulties caused by poor shift handover practices and/or team coordination problems or friction between team members.	10
6	A means of suppressing or overriding information or features which is too easily accessible.	9
7	No obvious means of reversing an unintended action.	9
8	Poor environment (lighting, heating, ventilation, physical access problems, e.g., rubble after explosion).	8
9	Operator inexperience.	8
10	Information overload, particularly one caused by simultaneous presentation of nonredundant information.	6
11	Poor, ambiguous, or ill-matched system feedback.	4
12	Shortfalls in the quality of information conveyed by procedures.	3
13	Operator underload/boredom.	3
14	A conflict between immediate and long-term objectives.	2.5
15	An incentive to use other more dangerous procedures.	2
16	No obvious way of keeping track of progress during an activity.	2
17	High emotional stress and effects of ill health.	2
18	Low workforce morale or adverse organizational environment.	2

of equation (2) prevents inadvertent reduction of the HEP by selecting a low APOA with a low maximum effect EPC. For example, if an APOA of 0.1 was selected for EPC 11, with the same GTT (C1), this would lead to a lower HEP than the original GTT:

$$HEP : 0.0004 \times 0.1 \times 2 = 0.00008 \quad (4)$$

Clearly this is not the intended outcome, so equation (2) avoids this problem. One other point to mention is that in some cases the multiplication factors push the HEP beyond the bounds of probability, e.g., producing an outcome value greater than unity (1.0), in which case the analyst must simply truncate the value at 1.0. As mentioned already, any HRA technique requires training and experience, and data sets (scenarios, factors, and actual – known – HEPs) are available with which HRA analysts can train themselves and “calibrate” their approach.

The example also highlights another useful function of this type of analysis. Of the two EPCs, which is most important if error reduction is required? In this particular example, the problem of unfamiliarity clearly dominates the human contribution to risk, so if error reduction is required, this would be the first port of call. This is a useful function, and HRA can help human factors prioritize issues – it may be far more effective and cheaper for example, to implement a refresher training regimen than provide an upgrade to the whole alarm system (HEART and SLIM also contain this function). NARA has its own error reduction guidance, and an extract for EPC 11 is given in Table 10.

A similarly flexible and quick HRA technique developed in the United States and applied on over 70 HRAs to date is the standardized plant analysis risk model human reliability assessment (SPAR-H) technique [22]. This uses an HEP calculation process

and a small number of PSF with associated quantitative multipliers to quantify HEPs for diagnosis and subsequent actions in nuclear power plants. It also contains guidance for dependence and uncertainty calculations.

Human error data. Human error probabilities would ideally be based on empirical data and stored in databases much as for reliability data in some industries. In fact, although there have been numerous human error databases over the years [23, 24], few have survived. One current human error database that is still growing is the computerized operator reliability and error database (CORE-DATA, [25]). This database has some high-quality data from nine separate industrial sectors, and has been the basis for development of NARA and a new approach for HRA in air traffic management (controller action reliability assessment, CARA [26]). Some example data from CORE-DATA is shown in Table 11.

As a general rule, for making an initial screening of HEPs, any task which is complex or time pressured may be considered as a first approximation to be in the 0.1–1.0 probability region. Routine tasks may be considered to be in the 0.01–0.1 region, and well-designed procedural tasks with good training, human interface, and checking can be considered to be in the 0.001–0.01 region. Such values should not themselves be used in an actual HRA, but are “rules of thumb” applied by assessors when first considering a range of tasks that may require quantification.

Human performance limiting values. Dependence has already been introduced *via* the THERP approach, which considers dependence between subsequent tasks. However, it is possible that a risk assessment failure path may contain several errors,

Table 10 Extract of NARA error reduction guidance for EPC 11: poor, ambiguous, or ill-matched system feedback

This EPC is clearly concerned with design aspects, so design is the optimum solution (e.g., using USNRC Doc NUREG 0700 or other ergonomic design guidance/standards). In particular, use unique coding of displays, and enhance discriminability of controls and displays *via* coding mechanisms (including color coding, grouping, etc.). For control panels, sometimes significant improvement can be made by enhanced labeling (e.g., hierarchical labeling schemes) and use of demarcation lines that highlight the functional groupings and relations between controls and control sequences. In some cases, however, the solution will entail either additional indications, including perhaps higher reliability, diversely measured, or more scenario-specific indications or alarms, or else relaying signals from external locations back to the main control room, to facilitate feedback in a centralized location. Procedures can help the operators focus on the best indicators and sets of indicators, and at least be aware of potential ambiguity problems. Training in a simulator with degraded indications can help prepare the operators for such scenarios (which are actually not uncommon in real events).

Table 11 Examples of HEPs from the CORE-DATA database^(a)

Study	Description of error	HEP	Data source
Nuclear (confidential)	During a shift the transport department brought a chemical load to the compound after permission had been arranged between two supervisors, but the correct paperwork did not arrive with the chemicals. Consequently this led to two cans of highly enriched chemical solution being processed instead of six cans of low enriched chemical.	0.0027	Real data
Manufacturing (confidential) Chemical [28]	A component has a different profile machined on each end. The operator inadvertently machines the aft end profile on the forward end. In a simulated chemical process plant, a trainee in a diagnostic task is faced with a panel of 33 instruments eight of which they were familiar with, eight they had never seen before. They had no feedback and had a limit of 5 min per problem. The error under consideration is incorrect diagnosis, including failure to diagnose.	0.00039 0.34	Hard copy data Simulator
Petrochemical [11]	Before the lifeboat is lowered to sea level, one of the internal checks that the coxswain must perform involves checking the air support system. This check was omitted. If the system is not checked and the crew find out after they have abandoned, there is the possibility of ingress of smoke. Lack of air will cause asphyxiation.	0.037	Simulator
Calculator errors [16]	An experiment is performed on a group of engineers selected from a large industry in America to investigate their performance in using electronic calculators. Each engineer is given a test and is required to calculate answers to numerical problems. The test consists of 10 problems ranging from very simple ones to more complex ones. Each problem is selected from the manual supplied with the calculator. The error of concern is that the engineer will make an error in the block of 10 problems.	0.27	Experimental data
Aviation [17]	A new system for data transfer and display for use by air traffic controllers is being evaluated in a simulation study. The simulation is based on normal flight operations at Heathrow Airport. The new system displays information to the controller on a single cathode ray tube which features a touch sensitive overlay on the display through which data is entered and controlled. The controller performs his normal duties, using the new system to transmit, obtain, and update information. There are three possible errors the controller can commit: miss touches, if the controller misses the area which should be touched; error touches, when the controller touches the wrong area; and illegal touches, when the controller touches a label out of sequence. In this scenario the air traffic controller makes a miss error.	0.064	Simulator data
Nuclear [18]	A locally operated valve has a rising stem and position indicator. An auxiliary operator, while using written procedures to check a valve line-up, fails to realize that the valve is not in the right position, after a maintenance person has performed a procedure intended to restore it to its proper position.	0.003	Expert judgment

^(a) Reproduced from [25]. © IEEE, 1997

all of which must happen, e.g., human error 1 (an initiating event error) AND human error 2 (a failure by an operator to detect the event) AND human error 3 (a failure to diagnose the event) AND human error 4 (a failure to recover the event). Even using dependence modeling as used in THERP, it is sometimes the case that such sequences (called *cutsets* in risk analysis terms) end up with a combined HEP that is unrealistically low (e.g., 0.000001). Incident and accident experience shows us in fact that although we try hard to model all failures, there are often surprises in store for us – things happen which were not predicted (e.g., an unpredicted EOC) or for reasons that were assumed to be implausible. This is also the case in hardware reliability and risk assessment, where in that domain cutsets are prevented from being optimistic by using limiting values or other methods (e.g., β factors). The same approach is necessary in HRA, so human performance limiting values (HPLVs) were developed [27]. Effectively, the general rule is not to allow the human error component of a cutset to go below 0.00001 or 10^{-5} , unless robust human error data exist to substantiate such low values or unless there are compelling qualitative arguments.

Validity of the HRA quantification approaches. Toward the end of the 1980s there were a number of techniques (around a dozen) in use in nuclear, process and chemical, and offshore oil and gas sectors of industry. In an effort to clarify the situation, a series of validations were carried out [29, 30]. In such exercises, HRA assessors were given task descriptions and asked to use their techniques to predict results for which the validators had data (and such data were not known by the assessors). Where prediction accuracy fell below a reasonable proportion (e.g., most HEPs needed to be predicted within a factor of 10, and preferably a factor of 3), the technique was invalidated. In such exercises, for example, THERP, absolute probability judgment (APJ), and HEART received positive validations, whereas SLIM's predictive accuracy depended critically on certain factors (notably "calibration" of the expert judgments) and was less assured. One approach in particular, which predicted human performance effectively solely as a function of time available to carry out the task (called *time response curve*) was invalidated [31, 32].

To show how validation works, the results of a large-scale UK validation [33] are summarized here,

which focused on the three quantification techniques THERP, HEART, and JHEDI. Totally 30 UK HRA practitioners took part in the exercise and each assessor independently used only one of the three techniques (very few assessors were practitioners in more than one technique). Each assessor quantified HEPs for 30 tasks, and for each task there were the following information:

- general description of the scenario;
- inclusion of relevant PSF information in the description;
- provision of simple linear task analysis;
- provision of diagrams where necessary and relevant;
- statement of exact human error requiring quantification.

Each assessor had 2 days to carry out the assessments, and experimental controls were exercised, so that the assessors were working effectively under invigilated examination conditions. For each of the 30 tasks the HEP was known to the experimenter, but not to any of the assessors. Tasks were chosen to be relevant to nuclear power and reprocessing industries, since all of the assessors belonged to these two areas. A large proportion of the data were from real recorded incidents, with the data range spanning five orders of magnitude (i.e., from 1.0 to $1\text{E}-5$).

The analysis of all data (i.e., all 895 estimated HEPs – there were five missing values) showed a significant correlation between estimates and their corresponding true values (Kendall's coefficient of concordance: $Z = 11.807$, $p < 0.01$). This supported the validity of the HRA quantification approach as a whole, especially as no assessors or outliers were excluded from these results. The analysis of all data for individual techniques shows a significant correlation in each case (using Kendall's coefficient of concordance): THERP, $Z = 6.86$; HEART, $Z = 6.29$; JHEDI, $Z = 8.14$; all significant at $p < 0.01$.

Individual correlations for all subjects are shown in Table 12. There are 23 significant correlations (some significant at $p < 0.01$ level) out of a possible 30 correlations. This is a very positive result, again supporting the validity of the HRA quantification approach.

Table 13 shows that there is an overall average of 72% precision (estimates within a factor of 10) for all assessors, irrespective of whether they were significantly correlated or not. This figure includes

Table 12 Correlations for each subject for the three techniques

	THERP	HEART	JHEDI
1	0.615**	0.577**	0.633**
2	0.581**	0.558**	0.551**
3	0.540**	0.473**	0.533**
4	0.521**	0.440**	0.452**
5	0.437**	0.389*	0.436**
6	0.311*	0.370*	0.423*
7	0.298	0.351*	0.418*
8	0.297	0.347*	0.401*
9	0.254	0.217	0.386*
10	0.078	0.124	0.275

* Significant at $p < 0.05$ ** Significant at $p < 0.01$

all data estimates, even the apparent outliers that have been identified in the study. This is therefore a reasonably good result, supporting HRA quantification as a whole. Furthermore, no single assessor dropped below 60% precision in the study. The precision within a factor of 3 is approximately 38% for all techniques. This is a fairly high percentage, given the required precision level of a factor of 3. The degree of optimism and pessimism is not too large, as also shown in the histogram in Figure 4, with only a small percentage of estimates at the extreme optimistic and pessimistic ends of the histogram (i.e., greater than a factor of 100 from the actual estimate). Certainly there is room for improvement, but the optimism and pessimism are not in themselves dominating the results, and estimates were more likely to be pessimistic (17.5% of the total number of estimates) than optimistic (9.7% of the total number of estimates), which means that assessors erred on the side of caution. The highest and lowest precision values for the techniques within a factor of 3 and within a factor of 10 are shown in Table 14.

The overall results were therefore positive with a significant overall correlation of all estimates with the known true values, with 23 individual (assessor)

significant correlations and a general acceptable precision range of 60–87%, the average precision being 72%. These results lend support for the HRA quantification part of the HRA process in general.

Second generation HRA. In the early 1990s a prominent HRA expert [34] suggested, on the basis of experiences of the accidents mentioned above, that most HRA approaches did not pay enough attention to context, i.e., to the detailed scenarios people found themselves in. Essentially, the argument was that considering human reliability in an abstracted format of fault and event trees was insufficient to capture the local situational factors that would actually dictate human behavior and lead to success or failure. This occurred at the same time as a growing concern in the United States in particular with EOC, wherein a human in the system does something that is erroneous and not required by procedures (e.g., shutting off emergency feed water to the reactor in Three Mile Island and disconnecting safety systems while running reactivity experiments in Chernobyl). Such errors of intention, relating to a misconception about the situation, are, as already noted earlier, severely hazardous to industries such as nuclear power and aviation. Incident experience in the United States was suggesting that it was these types of rare errors, whose very unpredictability made them difficult to defend against, which were of most real concern.

Therefore, work on a set of so-called second generation HRA techniques began in the early mid-1990s. The most notable of these were a technique for human error analysis (ATHEANA [35]), the cognitive reliability error analysis method (CREAM [36, 37]), MERMOS [38], and the connectionist approach to human reliability (CAHR) [39]. ATHEANA is notable because it has had more investment than almost any other HRA technique. The qualitative part of the method is intensive and is used for identification of safety critical human interventions in several instances, but its quantitative use has so far been marginal due to residual problems over

Table 13 Precision for the three techniques for all HRA assessors

	Factor 3 (%)	Factor 10 (%)	Optimistic (%)	Pessimistic (%)
THERP	38.33	72	13.67	13.33
HEART	32.67	70.33	11	18.33
JHEDI	43.67	75	3.33	21.33

Figure 4 Overall HRA optimism and pessimism

quantification. CREAM is a more straightforward quantification technique that has had some applications in the nuclear power domain. MERMOS is used only in France and focuses on the conditions that need to coincide to give rise to errors of commission. CAHR is similar to JHEDI in that it uses real incident data calibrated to generate HEPs, and has been used in HRAs/PSAs in Germany in several industries (JHEDI is in use in only one organization in the United Kingdom). The term second generation really refers to two aspects: the first is a more profound analysis of contextual factors (including interacting PSF) to ensure the accuracy and validity of the resultant HEPs (CREAM and CAHR, and to an extent JHEDI) and the second is the ability to predict errors of commission (ATHEANA) or the conditions that lead to them (MERMOS).

A recent international HRA expert workshop (Halden Reactor Project Workshop on HRA, October 2005, Halden, Norway) provided an overview of the current level of implementation of second generation approaches. Though the methods mentioned above were all applied already in various safety assessments, there is still more work to be done regarding the evidence of empirical validation compared to “first generation” techniques (like HEART or THERP). The level of application and work to be done can also be seen from a special issue of a key reliability journal on HRA and EOCs [40].

The second generation HRA approach is clearly still evolving. Taken to one extreme, there is less focus on individual errors and more focus on determining what factors can combine to lead to an intrinsically unsafe situation, wherein errors of intention become increasingly likely. This concept has some resonance not only with accidents such as the nuclear accident at Chernobyl or the chemical accident in Bhopal, India, but also with the Überlingen midair collision in 2002 in Germany. In the latter tragic event, although there were discrete air traffic controller and pilot errors that were arguably predictable by first generation HRA methods, there was nevertheless an aggregation of an unusually large amount of factors that predisposed the whole situation to failure. This “confluence” of negative factors is now also being looked at not only by HRA, but also by proponents of the new field of “resilience engineering” (see **Managing Infrastructure Reliability, Safety, and Security**) [41].

This does not mean that second generation HRA research should stop, nor does it mean that HRA is useless without this function of predicting errors of commission – HRA can still identify and predict most types of errors and occasionally errors of commission too. What it does mean for system developers and risk managers is that other methods and measures must be utilized, adopting a “defense in depth” strategy for managing human error, including maintaining

Table 14 Precision for the three techniques

	Highest precision		Lowest precision	
	Factor of 3 (%)	Factor of 10 (%)	Factor of 3 (%)	Factor of 10 (%)
THERP	56.67	80	10	63.33
HEART	46.67	76.67	16.67	60
JHEDI	66.67	86.67	26.67	70

a good level of human factors adequacy in the operator interfaces, environment, and support systems (training, procedures, work organization, etc.), as well as a good safety culture that will avoid or reduce violations and help detect the seeds of errors of commission long before they manifest themselves in accidents.

In practical terms, first generation techniques are still useful. Rather than second generation techniques being seen as an attempt to replace first generation HRA tools, a more likely future relationship is one of complementarity. For example, SPAR-H and ATHEANA could be an effective partnership for the US nuclear industry, and the European air traffic industry is similarly considering a similar dual approach involving CARA and an ATM-version of CAHR. Such partnerships may offer a more flexible and resource-efficient approach to HRA.

Safety culture. *Safety culture* concerns the degree to which the culture of the installation's organization puts safety and correct performance as the overriding priority. It came into being as an area of study and improvement following the 1986 Chernobyl disaster [42]. If everyone in the organization is personally concerned with safety, and mindful of error, and willing to question practices if they believe them to be unsafe, then clearly this has an impact on error reduction, error recovery enhancement, violation avoidance, as well as watching out for errors of commission.

Violations, in particular, are inextricably bound together with the concept of safety culture. An installation with a good safety culture should not exhibit rule violations, whereas one with a poor safety culture will exhibit routine and even perhaps, under certain circumstances, extreme violations. The concern with rule violations is similar to that for mistakes – violations can lead to failure of multiple safety systems and barriers. As an example, a risk assessment may assume that a fully programmed machine with multiple interlocks will not be used in “maintenance mode” (where the safety interlocks are disabled) for normal operations. Such a “routine” violation would not only violate the procedures of the installation, but would also seriously violate the assumptions of the risk analysis, such that its predictions of failure for such a system could easily be incorrect by one or more orders of magnitude.

When carrying out HRA and risk assessment in general, there are usually general assumptions made about the level of training and adherence to procedures. If there is a poor safety culture, the working assumptions of the risk assessment, at a certain point, will become invalid. This is to an extent what happened with both Bhopal and Chernobyl. No risk assessor would have assumed that so many safety systems would have been switched off or disabled.

There is a link, therefore between HRA (and risk assessment) and safety culture – ideally safety culture should be measured periodically (e.g., every 2 year) by an organization to verify that the “fundamentals” of adequate behavior and safe attitudes at work, which many would consider simply professional conduct, are being maintained.

HRA, Ethics, and “Just” Culture

An important standpoint of HRA is that it is not allocating blame – almost always, accidents and incidents and human errors are the result of system design and operational constraints, complexities, and pressures. Most errors are unintentional, and in the majority of tragic accidents, for example in aviation or rail, the human operator at the “sharp end” is not able to defend him or herself after the event. HRA therefore, as with risk assessment, aims to be dispassionate – the search is always for errors and their consequences, their causes, their relative importance, and effective (and sustainable) remedies. Even when an intentional error occurs or is predicted (e.g., a violation of procedures), the assessor is looking for deeper causes in the organizational culture (called *safety culture*). Only when malice is intended, and this is exceptionally rare in work-related systems, the real connotation of blame would come into the equation, and at such a point this would be out of the hands of HRA and into criminal investigation. This standpoint of HRA practitioners is more relevant than for risk analysts, since the former will be interviewing operators and management from the system under investigation (whether an existing system or one that is on the drawing board). HRA analysts are predicting how a workforce, or a pilot, or a train driver, or a surgeon could make serious errors, possibly leading to deaths – this naturally has to be handled sensitively. The HRA analyst must convey (and believe) that (s)he is there to support these operators

by finding system vulnerabilities and helping them and the parent organization overcome them.

This point is practical as well as ethical. If people think they will be prosecuted for “honest mistakes” then they will not tend to report them. This means that the organization and the wider community will not be able to learn from such errors or even discover them until a large-scale accident occurs. This is usually far too late to learn, in terms of the losses that have already occurred (e.g., fatalities and loss of equipment etc.), as well as the financial and public confidence losses that will follow for the organization and perhaps even the industry concerned, in the wake of large-scale accidents. HRA therefore works within what is called a *just culture* framework.

As a closing point, it has to be said that most of the time people “get it right” and accidents are rare. In general, systems are very safe and productive, and this is not possible without the human operator. Human reliability, particularly in mature systems where the right balance between humans and engineered safety functions has been found, is often exceptionally good. HRA can therefore also be seen as an approach to “continuous improvement”, ensuring that the human operators (and their managers) are able to be both safe and effective – the two usually go hand in hand.

Conclusion

HRA started in the 1960s and has grown to be a useful tool in many industries where the human operators play a critical role. It is now used qualitatively and/or quantitatively in nuclear, chemical, offshore oil and gas, defense, aviation and air traffic, space, and medical sectors. This is a testament to the success of the overall approach.

HRA has been used in many assessments to decide if the design is safe or reliable enough, and to determine how to improve the human reliability in the system’s performance. Although HRA’s evolution is far from over, there is a useful methodology and toolkit available for any industry wishing to focus on supporting, protecting, and enhancing its major asset – the human in the system.

BARRY KIRWAN

Imprecise Reliability

Most methods in reliability and quantitative risk assessment assume that uncertainty is quantified *via* precise probabilities, all perfectly known or determinable. For example, for system reliability, complete probabilistic information about the system structure is usually assumed, including dependence of components and subsystems. Such detailed information is often not available, owing to limited time or money for analyses or limited knowledge about a system. In recent decades, several alternative methods for uncertainty quantification have been proposed, some also for reliability. For example, fuzzy reliability theory (see **Near-Miss Management: A Participative Approach to Improving System Reliability**) [1] and possibility theory [2] provide solutions to problems that cannot be solved satisfactorily with precise probabilities. We do not discuss such methods, but restrict attention to generalized uncertainty quantification *via* upper and lower probabilities, also known as *imprecise probability* [3] (see **Ecological Risk Assessment**) or “interval probability” [4, 5]. During the last decade, upper and lower probability theory has received increasing attention, and interesting applications have been reported. See [6] for a detailed overview of imprecise reliability and many references. It is widely accepted that, by generalizing precise probability theory in a mathematically sound manner, with clear axioms and interpretations, this theory provides an attractive approach to generalized uncertainty quantification.

In classical theory, a single probability $P(A) \in [0, 1]$ is used to quantify uncertainty about event A . For statistics, probability requires an interpretation, the most common ones are in terms of “relative frequencies” or “subjective fair prices for bets”. The theory of lower and upper probabilities [3–5] generalizes probability by using lower probability $\underline{P}(A)$ and upper probability $\overline{P}(A)$ such that $0 \leq \underline{P}(A) \leq \overline{P}(A) \leq 1$. The classical situation, so-called precise probability, occurs if $\underline{P}(A) = \overline{P}(A)$, whereas $\underline{P}(A) = 0$ and $\overline{P}(A) = 1$ represents complete lack of knowledge about A . This generalization allows indeterminacy about A to be taken into account. Lower and upper probabilities can be interpreted in several ways. One can consider them as bounds for a precise probability, related to relative frequency of the event A , reflecting the limited information one has

about A . Alternatively, from subjective perspective, the lower (upper) probability can be interpreted as the maximum (minimum) price for which one would actually wish to buy (sell) the bet that pays 1 if A occurs and 0 if not. Generally, $\underline{P}(A)$ reflects the information and beliefs in favor of event A , while $\overline{P}(A)$ reflects such information and beliefs against A . Walley [3], from the subjective point of view, uses coherence arguments to develop theory for lower and upper probabilities and related statistical methods. His theory generalizes the Bayesian statistical theory (see **Common Cause Failure Modeling; Bayesian Statistics in Quantitative Risk Assessment; Group Decision; Subjective Probability**) for precise probabilities in a manner similar to “robust Bayesian methods” [7], where sets of prior distributions are used and data is taken into account *via* a generalized version of Bayes’ theorem. Important properties are that lower (upper) probability is superadditive (subadditive), i.e., $\underline{P}(A \cup B) \geq \underline{P}(A) + \underline{P}(B)$ ($\overline{P}(A \cup B) \leq \overline{P}(A) + \overline{P}(B)$) for disjoint A and B , and $\underline{P}(A) = 1 - \overline{P}(\bar{A})$, with $\bar{A}$ the complementary event to A [3–5]. An advantage of lower and upper probability is that one only requires limited input with regard to the uncertainties about the events of interest, and one can (in principle) always derive corresponding lower and upper probabilities for all events, *via* “natural extension” [3], if the inputs are not contradictory. This is attractive, as one normally can only meaningfully assess a limited number of characteristics of random quantities. Computation of the lower and upper probabilities according to the natural extension might be complicated, as constrained optimization problems must be solved. We discuss this topic in the section titled “Imprecise Reliability *via* Natural Extension”.

Walley [3] discussed many reasons why precise probability is too restrictive for practical uncertainty quantification. In reliability, the most important ones include limited knowledge and information about random quantities of interest, and possibly information from several sources that might appear to be conflicting if restricted to precise probabilities. Common aspects such as grouped data and censoring can be dealt with naturally *via* imprecision, and imprecise reliability offers attractive methods for inference in case data contain zero failures.

In recent years, there has been increasing research into statistical methods using lower and upper probabilities. Following Walley [3], most of this work has been on robust-Bayes-like inferences, where sets of

prior distributions are used for a parametric model. In particular, Walley's Imprecise Dirichlet Model (IDM) [8] for multinomial inferences is proving popular, though it is not undisputed (see the discussion in [8]). Some results on the application of the IDM to reliability problems are discussed in the section titled "Statistical Inference in Imprecise Reliability". An alternative statistical approach has been developed by Coolen, together with several coauthors [9–11]. It is called *nonparametric predictive inference* (NPI), and is explicitly aimed at only making limited modeling assumptions, in addition to available data. Some NPI results in reliability are also discussed in the section titled "Statistical Inference in Imprecise Reliability". In the section titled "Challenges for Research and Application", we discuss some research challenges for imprecise reliability.

Imprecise Reliability *via* Natural Extension

Most of traditional reliability theory concerns analysis of systems, with probability distributions assumed to be known precisely. An attractive generalization provided by imprecise reliability theory enables such analyses under partial knowledge of probability distributions. This involves constrained optimization problems, where the inference of interest is the function to be maximized and minimized, to provide upper and lower bounds for the inference, respectively, and where all information available is formulated *via* constraints on the set of possible probability distributions. From this perspective, many basic problems in reliability have already been studied, a detailed recent overview with many references is given in [6]. Utkin [12, 13] considered system reliability, and provided algorithms for the optimization problems. Example 1 [6] is a simple example of the possibilities of imprecise reliability in this context.

Example 1 [6]. Consider a series system consisting of two components, where only the following information about the reliability of the components is available. The probability of the first component to fail before 10 h is 0.01. The mean time to failure of the second component is between 50 and 60 h. We want to draw inferences on the probability of system failure after 100 h. The information provided does not suffice to deduce unique precise probability distributions on the times to failure of the components, so standard reliability methods which use precise

probabilities would require additional assumptions. However, this information does restrict the possible probability distributions for these components' times to failure, and imprecise reliability now enables the inference in terms of the sharpest bounds for the probability of system failure after 100 h, given that the probability distributions of the components' times to failure satisfy the constraints following from the information available. The information provided is extremely limited, and the corresponding bounds on the inferences are that the system will experience its failure only after at least 100 h with lower probability 0 and upper probability 0.99. Suppose now, however, that we add one more piece of information, namely, that the failure times of the two components are statistically independent. The upper probability of system failure after at least 100 h now becomes 0.59. The corresponding lower probability remains 0, which agrees with intuition, as the information on both components does not exclude that either one of them might fail before 100 h with probability 1.

Although very basic, such an approach is of great value. It can give answers to many questions of interest, on the basis of the information that is available. If the answer is considered to be too imprecise, then additional assumptions or information are needed. It then provides insight on the effect of the extra information on the upper and lower bounds of the inference. This approach also indicates whether information or assumptions are conflicting, as no probability distributions would exist that satisfy all constraints. In such cases, one has to reconsider the available information and assumptions. Utkin, partly in collaboration with several coauthors, has presented theory and methodology for many such imprecise reliability inferences for systems, including topics on monotone systems, multistate and continuum-state systems, repairable systems, and reliability growth for software systems [6]. Further topics in imprecise reliability, where natural extension provides exciting opportunities for inference under limited information, include the use of expert judgments (*see Default Risk; Meta-Analysis in Non-clinical Risk Assessment*) and a variety of topics in risk analysis and decision support [6]. There are still many research topics that need to be addressed before a major impact on large-scale applications is possible.

Statistical Inference in Imprecise Reliability

Walley [3] developed statistical theory based on lower and upper probabilities, where many of the models suggested are closely related to Bayesian statistical methods with sets of prior distributions instead of single priors. An increasingly popular example is Walley's IDM [8] for multinomial observations. The multinomial distribution provides a standard model for statistical inference if a random quantity can belong to any one of $k \geq 2$ different categories. In the Bayesian statistical framework [14], Dirichlet distributions are natural conjugate priors for the multinomial model, so corresponding posteriors are also Dirichlet distributions. A convenient notation is as follows. Let exchangeable random quantities X_i have a multinomial distribution with $k \geq 2$ categories $C_1, \dots, C_k$ and parameter $\theta = (\theta_1, \dots, \theta_k)$, with $\theta_j \geq 0$ and $\sum_j \theta_j = 1$, then $P(X \in C_j | \theta) = \theta_j$. A Dirichlet distribution with parameters $s > 0$ and $t = (t_1, \dots, t_k)$, where $0 < t_j < 1$ and $\sum_j t_j = 1$, for the k -dimensional parameter θ , has probability density function (pdf) $p(\theta) \propto \prod_{j=1}^k \theta_j^{s t_j - 1}$. Suppose that data are available, consisting of the categories to which the random quantities $X_1, \dots, X_n$ belong, and that n_j of these belong to category C_j , with $n_j \geq 0$ and $\sum_j n_j = n$. The likelihood function corresponding to these data is $L(\theta | n_1, \dots, n_k) \propto \prod_{j=1}^k \theta_j^{n_j}$. Bayesian updating leads to the posterior pdf

$$p(\theta | n_1, \dots, n_k) \propto \prod_{j=1}^k \theta_j^{n_j + s t_j - 1} \quad (1)$$

This is again a Dirichlet distribution, with, compared to the prior, s being replaced by $n + s$ and t_j by $\frac{n_j + s t_j}{n + s}$.

Walley [8] introduced the IDM as follows. For fixed $s > 0$, define $D(s)$ as the set of all Dirichlet (s, t) distributions, so the k -vector t varies over all values with $t_j > 0$ and $\sum_j t_j = 1$. The set of posterior distributions corresponding to $D(s)$, in case of data $(n_1, \dots, n_k)$ with $\sum_j n_j = n$, is the set of all Dirichlet distributions with pdf given by equation (1), with $t_j > 0$ and $\sum_j t_j = 1$. For any event of interest, the lower and upper probabilities according to the IDM are derived as the infimum and supremum, respectively, of the probabilities for this event corresponding to Dirichlet distributions

in this set of posteriors. For example, if one is interested in the event that the next observation, X_{n+1} , belongs to C_j , then the IDM gives lower probability $\underline{P}(X_{n+1} \in C_j | n_1, \dots, n_k) = \frac{n_j}{n+s}$ and upper probability $\overline{P}(X_{n+1} \in C_j | n_1, \dots, n_k) = \frac{n_j + s}{n+s}$. The parameter s must be chosen independently of the data, Walley [8] advocates the use of $s = 1$ or 2 , on the basis of agreement of inferences with frequentist statistical methods.

The most obvious relevance of the IDM for reliability is with $k = 2$, when it reduces to the binomial distribution with a set of beta priors [3]. Binomial data often occur in reliability when success–failure data are recorded, for example, when the number of faulty units over a given period of time is of interest. In case of system reliability, one often records data at all relevant levels (components, subsystems, system) in terms of success or failure to perform their task. Hamada *et al.* [15], showed how, in a standard Bayesian approach with precise probabilities, binomial distributions with beta priors at component level can be used, for a given system structure (e.g., expressed via a fault tree), together with failure data gathered at different levels. For example, some observations would just be “system failure”, without detailed knowledge of which component(s) caused the failure. Such multilevel data incur dependencies between the parameters of the components' failure distributions. Hamada *et al.* [15], showed how Markov Chain Monte Carlo (MCMC) (*see Nonlife Loss Reserving; Reliability Demonstration; Bayesian Statistics in Quantitative Risk Assessment*) can be used for such inferences. Researchers have recently attempted to combine this approach with the IDM. Wilson *et al.* [16], applied the IDM to the same setting with multilevel failure data, although they expanded the binary approach from [15] to data with three categories (“failure”, “degraded”, “no failure”). They solve the computational problem, which is far more complex under imprecision than when precise probabilities are used, by brute force, as they perform multiple MCMCs, by first creating a fine grid over the space of prior distributions in the IDM, then running MCMC for each to derive the corresponding posterior probabilities, and finally computing the bounds over these. This only derives an upper (lower) bound for the lower (upper) probability, but if the MCMCs have been run long enough to ensure good convergence, and very many have been run, one is confident that

such a brute method provides good approximations to the lower and upper probabilities. This indicates a major research challenge for imprecise probabilistic statistical inference, namely, fast algorithms for computation. It is likely that optimization methods can be combined with simulation-based methods like MCMC in a way that requires less computational effort than the method presented in [16].

Troffaes and Coolen [17] generalized the approach from [15] differently. First, restricting to $k = 2$, they analytically derive the IDM-based upper and lower probabilities for system and component failure for a very small system (two components) and multilevel failure data. Then, they delete the usual assumption of independence of the two components, and show how the IDM can be used for inference without any assumption on such independence, and also if there may be unknown bias in data collecting and reporting. These are situations that cannot be solved with precise probabilities without additional assumptions. Other reliability methods and applications of IDM include inference for survival data including right-censored observations [18] and reliability analysis of multistate and continuum-state systems [19].

Imprecise probability enables inferential methods based on few mathematical assumptions if data are available. Coolen, with a number of coauthors, has developed NPI, where inferences are directly on future observable random quantities, e.g., the random time to failure of the next component to be used in a system. In this approach, imprecision depends in an intuitively logical way on the available data, as it decreases if information is added, yet aspects such as censoring or grouping of data result in an increase of imprecision. Foundations of NPI, including proofs of its consistency in theory of interval probability, are presented in [9], an overview with detailed comparison to so-called objective Bayesian methods is given in [10]. A first introductory overview of NPI in reliability is presented in [11], and theory for dealing with right-censored observations in NPI in [20, 21]. This framework is also suitable for guidance on high reliability demonstration, considering how many failure-free observations are required to accept a system in a critical operation [22]. The fact that, in such situations, imprecise reliability theory allows decisions to be based on the more pessimistic one of the lower and upper probabilities, e.g., lower probability of failure-free operation (*see Availability and Maintainability*), is an intuitively attractive manner

for dealing with indeterminacy. Recently, Coolen also considered probabilistic safety assessment from similar perspective [23]. NPI can also be used to support replacement decisions for technical equipment [24], giving decision support methods that are fully adaptive to failure data, and with imprecision reflected in bounds of cost functions. NPI can provide clear insights into the influence of a variety of assumptions that are often used for more established methods, and that may frequently be rather unrealistic if considered in detail. The fact that NPI can do without most of such assumptions and still be useful under reasonable data requirement is interesting.

Recent developments of NPI in reliability include the use of a new method for multinomial data for inferences on the possible occurrence of new failure modes [25] (see Example 3), and comparison of groups of success–failure data with specific attention to groups with zero failures [26]. To illustrate the use of NPI in reliability, we include two examples with references for further details.

Example 2 [11]. Studying 400 pumps in eight pressurized water reactors in commercial operation in the United States in 1972, six pumps failed to run normally for that whole year [14]. If we assume that all pumps are replaced preventively after 1 year, for example, to avoid failure due to wear-out, and that the pumps and relevant process factors remain similar, then it may be relevant to consider NPI for the number of failing pumps out of 400 during the following year, giving the lower and upper probabilities presented in Table 1 (upper probabilities for not-reported r values are less than 0.001).

Such lower and upper probabilities provide insight into the evidence in favor and against these particular events. Lower and upper probabilities for a subset of possible values cannot be derived by summing up the corresponding values in Table 1, because of the superadditivity (sub-) of lower (upper) probabilities, see [27] for more general results. This approach has the advantage over Bayesian methods [14] that no prior distributions are required, and their properties are such that they combine attractive features from both Bayesian and frequentist statistics [10].

Example 3 [25]. Suppose that a database contains detailed information on failures experienced during warranty periods of a particular product. Currently 200 failures have been recorded, with five different failure modes specified. The producer is interested in

Table 1 Lower and upper probabilities for r out of 400 pumps failing

r	$\underline{P}(r)$	$\overline{P}(r)$
0	0.0076	0.0153
1	0.0230	0.0541
2	0.0406	0.1088
3	0.0545	0.1641
4	0.0616	0.2059
5	0.0618	0.2270
6	0.0568	0.2273
7	0.0488	0.2111
8	0.0396	0.1844
9	0.0308	0.1533
10	0.0230	0.1222
11	0.0167	0.0939
12	0.0118	0.0700
13	0.0081	0.0508
14	0.0054	0.0359
15	0.0036	0.0249
16	0.0023	0.0169
17	0.0015	0.0113

the event that the next failure of such a product during its warranty period is caused by a failure mode other than the five already recorded. Let us first assume that there is no clear assumption or knowledge about the number of possible failure modes. Suppose that interest is in the event that the next reported failure is caused by an as yet unseen failure mode, then the NPI upper probability for this event is equal to $5/200$ [25]. If, however, the producer has actually specified two further possible failure modes, which have not yet been recorded so far, and interest is in the event that the next failure mode will be one of these two, then the NPI method gives upper probability $2/200$. This holds for any pair of such possible new failure modes that one wishes to specify, without restrictions on their number: this is possible because of the subadditivity of upper probability, which is an advantage over the use of precise probabilities. The NPI lower probabilities for both these events are zero, reflecting no strong evidence in the data that new failure modes can actually occur.

Now suppose that these 200 failures were instead caused by 25 different failure modes. Then the upper probability for the next failure mode to be any as yet unseen failure mode changes to $25/200$, but the upper probability for it to be either of any two described new failure modes remains $2/200$. It is in

line with intuition that the changed data affect this first upper probability, because the fact that more failure modes have been recorded suggests that there may be more failure modes. For the second event considered, the reasoning is somewhat different, as effectively interest is in two specific, as yet unseen, failure modes, and there is no actual difference in the data available that is naturally suggesting that either of these two failure modes has become more likely. If the producer has specific knowledge on the number of possible failure modes, that can also affect these upper probabilities [25].

Challenges for Research and Application

Imprecise probabilistic methods in reliability and risk assessment have clear practical advantages over more established and more restricted theory with precise probabilities. Owing to the possible interpretations of lower and upper probabilities, they are often convenient for practical risk assessment, as they reflect both “pessimistic” and “optimistic” inference. It is often clear on which of these to base decisions, for example, one would focus on the upper probability of an accident to occur.

Imprecise reliability is still at an early stage of development [6, 28], as are general theory and applications of lower and upper probabilities. There are many research challenges, ranging from foundational aspects to development of implementation tools. Upscaling from “textbook style” examples to larger scale problems provides many challenges, not only for computational methods but also e.g., for effective elicitation of expert judgment. At the foundational level, further study of the relation between imprecision and (amount of) information is required [29].

There is huge scope for new models and methods in imprecise reliability, and further development of some methods is required. For example, Utkin and Gurov [30] presented attractive classes of lifetime distributions, with $H(r, s)$, for $0 \leq r \leq s$, the class of all lifetime distributions with cumulative hazard function $\Lambda(t)$ such that $\Lambda(t)/t^r$ increases and $\Lambda(t)/t^s$ decreases in t . For example, $H(1, \infty)$ are all distributions with increasing hazard rates. Some results for related inference have been presented [30], but interesting research problems are still open, including how to fit such classes to

available data. The IDM and NPI have shown promising opportunities for applications in reliability, but statistical theory must be developed further to enhance applicability, for example, on the use of covariates and generalization to multivariate data.

FRANK P.A. COOLEN AND LEV V. UTKIN

Individual Risk Models

Insurance is protection against uncertainty. A contract (*policy*) between the insurance company (*insurer*) and a policyholder (*insured*) states that while the insurer pays a specified amount of money (also called *premium*) to the insurance company, in return, the company will compensate any loss suffered by the insured as a result of a specified random event (*claim*). A policy may include specific provisions that reduce the insurer's obligation (e.g., *deductibles*). Similar policies are grouped in an insurance portfolio.

If at a certain point of time the amount of surplus of the insurer becomes negative, then it is ruined. To avoid ruin, an insurance company sets apart some financial reserves and also buys risk protection from a reinsurance company (*see Credit Risk Models; Reinsurance; Securitization/Life*). There are various forms of reinsurance covers for the insurance portfolios.

To track the surplus, the claim payments must be modeled. This is why, for an insurance company, studying the aggregate claims distribution (*see Bonus–Malus Systems; Comonotonicity*), that is, the distribution of the aggregate amount of insurance claims occurring in an insurance portfolio within a given period, is of crucial importance (e.g., for premiums calculation, for evaluating the ruin probability and the needed reserves, for studying the effect of deductibles and reinsurance covers).

There are two main ways to model aggregate claims distributions; individual and the collective models. In the collective risk model, the aggregate claims of the portfolio is the sum of the individual claims (considered as independent and identically distributed), their number being a random variable (i.e., the number of claims arising in the considered period) independent of the payment amounts (*severities*). This decomposition allows consideration of claims number and claims amounts separately.

In an individual risk model, the aggregate claims of the portfolio is the sum of the aggregate claims of each of the policies. Thus, while in the collective model the claims are not related to the policies and the group of policies is taken as a whole (hence the name *collective*), in the individual model, the claims are related to the individual policies and

then aggregated to the portfolio (therefore the name *individual*).

In the following, we restrict ourselves to the individual risk model (*see Inequalities in Risk Theory*). Assuming that the policies (also called *risks*) in the portfolio are independent, it is straightforward to calculate the distribution of the sum of their aggregate claims by using convolutions. But this technique can be quite laborious, hence, alternative methods, such as recursive methods, have been investigated. Most of the recursions that have been derived for the general individual risk model can be considered as generalizations of [1].

A survey of recursions for aggregate claims distributions can be found in [2], while an overview of these recursive methods, in the framework of the individual risk model, is given in [3]. For a more detailed study of recursions grouping in the existing literature, we refer to [4].

The structure of this paper is as follows: we start by describing the individual risk model, then we present two exact recursions for it, followed by the three main approximative recursions. We end with other alternative methods and a numerical example.

In the following, we shall refer to probability functions as distributions, the sum over an empty set is assumed to be equal to zero, and we let $[x]$ denote the largest integer less than or equal to x .

Model Description

In the general individual risk model, the portfolio consists of n independent policies of different types. For each type, the aggregate claims distribution and the number of policies of that type is known; the distribution of the aggregate claims S of the entire portfolio is to be evaluated. A particular case of this model, well studied in the literature, assumes that the portfolio is divided into classes by clustering all policies with the same probability of a strictly positive claim amount and with the same severity distribution, as displayed in Table 1. The severity distribution (*see Dependent Insurance Risks; From Basel II to Solvency II – Risk Management in the Insurance Sector*) of a policy corresponds to the conditional distribution of the claim amount, given that a claim has occurred.

For the resulting two-way classification model, the class (i, j) , $i = 1, \dots, a$, $j = 1, \dots, b$, contains

Table 1 Portfolio structure for the two-way classification model

Claim amount distribution		Claim probability				
		q_1	q_2	$\cdots$	q_j	$\cdots$
	g_1					
	g_2				$\cdots$	
	$\cdots$					
	g_i			$\cdots$	n_{ij}	
	$\cdots$					
	g_a					

all policies with severity distribution g_i and claim probability q_j . The number of policies in class (i, j) is denoted by n_{ij} . It is assumed that for each j , $0 < q_j < 1$, and that the claim amounts of the individual policies are positive integers representing multiples of some convenient monetary unit, so that for each i , $g_i(x)$ is defined for $x = 1, 2, \dots$.

The probability that the aggregate claims $S = s$ is denoted by $f(s)$. We also use the notation $p_j = 1 - q_j$ and $n_{+j} = \sum_{i=1}^a n_{ij}$.

The case where the individual claim amounts can take only one strictly positive value, i.e., for each i , g_i is concentrated in one value, has been called the *individual life model* because of its straightforward application in life insurance: the portfolio consists of life insurance policies, and the corresponding strictly positive value is the benefit payable if death occurs within a certain exposure period.

Back to the general model, to see the applicability of the distribution of the aggregate claims S , we consider the following example in which the surplus U of a portfolio after a certain time period (e.g., 1 year), is given by

$$U = u + \pi - S \quad (1)$$

where π and S are respectively the portfolio's premium income and aggregate claims at the end of the period, while u is the initial reserve. Then the ruin probability (see **Longevity Risk and Life Annuities; Large Insurance Losses Distributions; Risk Measures and Economic Capital for (Re)insurers; Solvency; Ruin Probabilities: Computational Aspects**) at the end of the considered time period is

$$\psi(u) = \Pr(U < 0) = \Pr(S > u + \pi) \quad (2)$$

which can be evaluated knowing the distribution of S . From formula (2), one can also easily determine

the minimum reserve u needed to keep the ruin probability ψ under a maximum threshold imposed by the insurer, and hence decide whether reinsurance is needed. Similar formulae can be used to study how different types of reinsurance could affect the ruin probability of this particular portfolio.

In the following, we will present exact and approximative recursions for the two-way classification model, as developed initially. These recursions can be extended to the general individual risk model (see [5]).

Exact Recursions

We start by presenting recursions for the exact computation of the aggregate claims probabilities f .

De Pril's Exact Recursion

Using probability generating functions, De Pril [6] obtained the following exact recursion,

$$f(0) = \prod_{j=1}^b p_j^{n_{+j}} \quad (3)$$

$$f(s) = \frac{1}{s} \sum_{i=1}^a \sum_{k=1}^s A(i, k) \times \sum_{x=k}^s x g_i^{*k}(x) f(s-x), \quad s = 1, 2, \dots \quad (4)$$

with

$$A(i, k) = \frac{(-1)^{k+1}}{k} \sum_{j=1}^b n_{ij} \left(\frac{q_j}{p_j} \right)^k \quad (5)$$

and g_i^{*k} denoting the k -fold convolution of g_i . In our case,

$$g_i^{*k}(s) = \sum_{x=1}^{s-k+1} g_i^{*(k-1)}(s-x) g_i(x), \quad k = 2, \dots, s \quad (6)$$

since $g_i(x)$ is defined for $x \geq 1$, we must have $s-x \geq k-1$.

Dhaene–Vandebroek's Recursion

Dhaene and Vandebroek [7] proposed the following exact recursive formula

$$f(s) = \frac{1}{s} \sum_{i=1}^a \sum_{j=1}^b n_{ij} v_{ij}(s), \quad s = 1, 2, \dots \quad (7)$$

with the initial value given as before by formula (3), and where the $v_{ij}s$ are determined by

$$v_{ij}(s) = \frac{q_j}{p_j} \sum_{x=1}^s g_i(x) (x f(s-x) - v_{ij}(s-x)), \quad s = 1, 2, \dots \quad (8)$$

and $v_{ij}(s) = 0$ otherwise.

When $a = b = 1$, Dhaene–Vandebroek's recursion can be reduced to Panjer's recursion [8] with binomial counting distribution.

Approximations

To reduce the computing time, approximating f by a function $f^{(r)}$ was suggested. The three most well-known classes of such approximations are De Pril, Kornya, and Hipp.

Although f is a distribution, unfortunately, this is not always the case with $f^{(r)}$ (e.g., De Pril's and Hipp's approximations are not proper distributions). Another possible lack of an approximation is that its moments don't usually match the corresponding moments of the exact distribution, even for lower orders (this is the case with De Pril's and Kornya's approximations). Therefore, to measure the quality of different approximations, error measures were introduced and studied in the literature.

De Pril's Approximation

The De Pril approximation was introduced by De Pril [9] for the individual life model and De Pril [6] for the general model. This r th order approximation is obtained by simply summing up to $k = r$ in formula (4), that is

$$f^{(r)}(s) = \frac{1}{s} \sum_{i=1}^a \sum_{k=1}^{\min\{r,s\}} A(i, k) \sum_{x=k}^s x g_i^{*k}(x) f^{(r)}(s-x),$$

$$s = 1, 2, \dots \quad (9)$$

with the same initial value of formula (3), and the coefficients A given by formula (5).

Kornya's Approximation

Introduced by Kornya [10] for the individual life model and by Hipp [11] for the general model, Kornya's approximation is equal to De Pril's approximation up to a multiplicative constant chosen so that $f^{(r)}$ sums to one like a probability distribution. Thus, formula (9) is the same, but now we have the initial value

$$f^{K(r)}(0) = \exp \left(\sum_{j=1}^b n_{+j} \sum_{k=1}^r \frac{(-1)^k}{k} \left(\frac{q_j}{p_j} \right)^k \right) \quad (10)$$

Hipp's Approximation

Introduced by Hipp in [11], this approximation has the property that its moments match the moments of the exact distribution up to the order of the approximation, as shown in [12]. It follows that

$$f^{H(r)}(0) = \exp \left(- \sum_{j=1}^b n_{+j} \sum_{k=1}^r \frac{q_j^k}{k} \right) \quad (11)$$

$$f^{H(r)}(s) = \frac{1}{s} \sum_{x=1}^s x h^{(r)}(x) f^{H(r)}(s-x), \quad s = 1, 2, \dots \quad (12)$$

with

$$h^{(r)}(x) = \sum_{i=1}^a \sum_{j=1}^b n_{ij} \sum_{k=1}^{\min\{r,x\}} \sum_{l=1}^k \frac{(-1)^{l+1}}{k} \binom{k}{l} \times q_j^k g_i^{*l}(x), \quad x = 1, 2, \dots \quad (13)$$

Compared with the other approximations, Hipp's approximation requires more computation time.

Error Bounds

De Pril [6] compared these three approximations and deduced error bounds based on the error measure $\varepsilon(f, f^{(r)}) = \sum_{s=0}^{\infty} |f(s) - f^{(r)}(s)|$, separately

for each of the approximations. The deduction of the error bounds was unified in [13]. Dhaene and Sundt [14] deduced more inequalities for the error measure ε .

Computational Aspects

The efficiency of the different exact and approximate recursions, in terms of the number of computations required (especially multiplications and divisions), and the size of the array of the data to be kept, has been investigated partly in [7] and complemented in [3]. These authors concluded that if an exact recursive method is required, Dhaene–Vandebroek’s recursion will be the optimal choice, if the portfolio is not too heterogeneous. A similar comparison with two alternative binomial methods was conducted in [15], who showed that in some situations, a binomial or a combined method can perform better. In most practical cases, however, depending on the level of accuracy required, an “ r th order approximation” can be the best choice. From numerical examples (see [16]) and also from the error bounds for the approximations, it follows that in practical situations, with values of the claim probabilities q_j small enough (e.g., smaller than 1/2), the approximations for the probabilities converge very quickly to their respective exact values, so that a choice of r equal to 3, 4, or 5 will give almost exact results.

Also, a practical comparison of the compound Poisson approximation with De Pril’s, Kornya’s, and Hipp’s methods is given in [17].

Alternative Methods

Transforming the Individual Model

In the literature, there are other methods leading to recursive formulae for the individual model. For example, the individual model could be replaced by a collective one, and then the recursion of Panjer [8] to evaluate the associated compound distribution could be used. Such an approach leading to a compound Poisson model (see **Volatility Smile**) is described e.g., in [18] and [19]; the compound binomial model is presented in [20]; and generalizations can be found in [21]. (See also [22–27].) An overview and extensions of such results are presented in [28].

Sundt [29] proposed a “natural” approximation in which the original portfolio is replaced by a

homogeneous one. Here the distribution of S is approximated on the basis of convolutions calculated using the recursive formula described in [30].

The De Pril Transform

Inspired by De Pril [6], Sundt [31] introduced the De Pril transform of a distribution defined on the nonnegative integers with positive probability at zero. He noticed that for any such distribution f , there exists a unique function φ_f such that

$$f(s) = \frac{1}{s} \sum_{x=1}^s \varphi_f(x) f(s-x), \quad s = 1, 2, \dots \quad (14)$$

He called φ_f the De Pril transform of f . Solving equation (14) for $\varphi_f(s)$ gives

$$\varphi_f(s) = \frac{1}{f(0)} \left(s f(s) - \sum_{x=1}^{s-1} \varphi_f(x) f(s-x) \right) \\ s = 1, 2, \dots \quad (15)$$

As f should sum to one, its De Pril transform is unique. Several results concerning De Pril’s transform are presented in [31–33].

The De Pril transform can be used to express the exact and approximative recursions described in the sections titled “Exact Recursions” and “Approximations” in a unified form, based on formula (14). For example, De Pril’s exact recursion (formula 4) can be rewritten as formula (14) with

$$\varphi_f(x) = x \sum_{k=1}^x \frac{(-1)^{k+1}}{k} \sum_{j=1}^b \left(\frac{q_j}{p_j} \right)^k \sum_{i=1}^a n_{ij} g_i^{*k}(x), \\ x = 1, 2, \dots \quad (16)$$

Similarly, for De Pril’s approximative recursion (formula 9), one can use formula (14) with f replaced by $f^{(r)}$, and the sum in formula (16) up to $k = \min\{r, x\}$. The initial value of formula (3) is the same.

We notice that Hipp’s approximation is already in the form (14) with $\varphi_{f^{H(r)}}(x) = x h^{(r)}(x)$.

Dhaene and Sundt [32] also extended the definition of the De Pril transform to the class of all functions on the nonnegative integers with positive mass at zero.

Special Case: Individual Life Model

$$s = 1, 2, \dots \quad (18)$$

Recursions for this particular case have been derived in [34, 35] with

As mentioned before, the individual life model is obtained from the two-way classification individual risk model considered above, by choosing

$$g_i(x) = \begin{cases} 1, & x = c_i \\ 0, & \text{otherwise} \end{cases}, \quad i = 1, 2, \dots, a \quad (17)$$

with c_i the amount at risk (e.g., for a life insurance policy, the benefit payable if death occurs) of the policies in row i . In this case, the recursion in formula (4) reduces to

$$f(s) = \frac{1}{s} \sum_{i=1}^a \sum_{k=1}^{[s/c_i]} a(i, k) f(s - kc_i),$$

$$a(i, k) = (-1)^{k+1} c_i \sum_{j=1}^b n_{ij} \left(\frac{q_j}{p_j} \right)^k \quad (19)$$

This recursion was first derived in [34].

In the individual life model, the $v_{ij}s$ in formula (8) reduce to

$$v_{ij}(s) = \frac{q_j}{p_j} (c_i f(s - c_i) - v_{ij}(s - c_i)),$$

$$s = 1, 2, \dots \quad (20)$$

and the recursion in formula (7) with formula (20) is due to Waldmann [35]. Waldmann obtained his results by a rearrangement of the recursive scheme of De Pril [34] and showed that his exact recursive scheme is more efficient than the original algorithm of De Pril.

Recursions for the number of policies that lead to a strictly positive claim amount are obtained from formulas (18) and (20) by setting all c_i equal to 1. In this case, the recursion of De Pril [34] given in formula (18) reduces to the recursion of White and Greville [1].

Numerical Example

To illustrate the accuracy of the three approximations presented in the section titled “Approximations”, we consider the portfolio of Gerber [18], also used by several authors (see [11, 16, 20, 21, 29]). This portfolio corresponds to the individual life model with $a = 5$ and $c_i = i, i = 1, \dots, 5$ (see Table 2).

In Tables 3 and 4 we give the probability function and cumulative distribution $\Pr(S \leq s)$ of the portfolio calculated according to various algorithms, where *exact* stands for exact values, while $D(r)$, $K(r)$, and $H(r)$ respectively stand for De Pril's, Kornya's, and Hipp's approximations of order r . In the last line, we also show the value of the ε error measure defined in the section titled “Error Bounds”.

All the numerical values, ε excepted, are truncated after five decimals. This explains the fact that for $r = 4$ the values of the three approximations equal the exact values for $s = 0, \dots, 25$. Also, because of

a close similarity with the exact values, we did not show the approximated values for $r = 3$. Yet, we have the following error values:

$$\begin{aligned}\varepsilon(\text{Exact}, D(3)) &= 5.2212 \times 10^{-5}; \\ \varepsilon(\text{Exact}, D(4)) &= 2.3722 \times 10^{-6} \\ \varepsilon(\text{Exact}, K(3)) &= 8.7261 \times 10^{-5}; \\ \varepsilon(\text{Exact}, K(4)) &= 4.2989 \times 10^{-6} \\ \varepsilon(\text{Exact}, H(3)) &= 1.3529 \times 10^{-4}; \\ \varepsilon(\text{Exact}, H(4)) &= 1.0774 \times 10^{-5}.\end{aligned}$$

In conclusion, this numerical example supports the fact that a choice of $r \geq 4$ shall give almost exact results, and from the error values ε , it seems that De Pril's approximation converges faster.

Inequalities in Risk Theory

Consider an insurance portfolio containing n risks. The risks may have different distribution functions belonging to a known parametric family of distributions. For example, consider a life insurance portfolio with hidden heterogeneity, due to different backgrounds of the insureds, that is unknown to the insurer. We would like to compare the premia between two portfolios with different amounts of heterogeneity, when all the insureds pay the same premium. In this paper we examine the impact of heterogeneity on the portfolio's risk measure. A risk measure function ρ assigns to each nonnegative random variable a nonnegative number. For example, a premium can be viewed as a risk measure. The larger the value of $\rho(X)$, the more dangerous the risk X , and thus more capital is required to hedge this risk. Specifically, we expect that $\rho(X) \geq \rho(\mathbb{E}(X))$, where $\mathbb{E}(X)$ is the mean of the random variable X . Let g be an increasing convex function. The risk measure defined by $\rho(X) = \mathbb{E}g(X)$ has many desirable properties; especially note that according to Jensen's inequality $\mathbb{E}[g(X)] \geq g(\mathbb{E}[X])$. For a comprehensive overview on risk measures (see **Risk Classification/Life**), see Denuit and Frostig [1].

Consider two portfolios: portfolio I contains the risks $(X_1, \dots, X_n)$ and portfolio II contains the risks $(Y_1, \dots, Y_n)$. Assume that the distribution functions of X_i and Y_i , $i = 1, \dots, n$ belong to the same parametric family of distributions. Let $\theta = (\theta_1, \dots, \theta_n)$ and $\eta = (\eta_1, \dots, \eta_n)$, be the vectors of parameters of the distribution functions of the risks in portfolio I and II, respectively. Let η be more heterogeneous or, more diverse, in a sense that will be defined later, than θ . The goal of this paper is to study the impact of the increase in the heterogeneity on the portfolio's risk measure.

There is no definite answer to the question whether heterogeneity reduces or increases risk, and the answer depends on the type of heterogeneity. An example where heterogeneity increases risk was studied by Denuit and Vermandele [2]. They considered a portfolio containing n independent identically distributed (i.i.d.) risks $X_1, \dots, X_n$, and functions $\psi_1, \dots, \psi_n$ with $\bar{\psi}(x) = \frac{1}{n} \sum_{j=1}^n \psi_j(x)$. They proved that the loss $\sum_{j=1}^n \bar{\psi}(X_j)$ is preferred over

$\sum_{j=1}^n \psi_j(X_j)$ by all decision makers, with nondecreasing and concave utility functions.

On the other hand, the following example demonstrates that heterogeneity reduces risk. Consider two portfolios each containing two risks. Let the first one be (X_1, X_2) and the second one be (Y_1, Y_2) . Let $X_i = J_{p_i} C_i$ and $Y_i = J_{q_i} C_i$, $i = 1, 2$, where C_1, C_2 denote the claim amounts and are identically distributed with mean μ and variance σ^2 . J_{p_i} equals 1 with probability p_i , and 0 with probability $1 - p_i$. It indicates whether a claim arose for policy i . All the random variables involved are independent. Assume further that $p_1 + p_2 = q_1 + q_2$ and that $p_2 - p_1 < q_2 - q_1$. Thus, the vector $\mathbf{q} = (q_1, q_2)$ is more heterogeneous than $\mathbf{p} = (p_1, p_2)$. Note that the mean of total payout is the same for the two portfolios. Let us measure the risk by the variance of the total payout.

$$\begin{aligned} \text{Var}[X_1 + X_2] &= (\sigma^2 + \mu^2)(p_1 + p_2) - \mu^2(p_1^2 + p_2^2) \\ &= (\sigma^2 + \mu^2)(p_1 + p_2) - \frac{\mu^2}{2} \\ &\quad \times \left((p_1 + p_2)^2 + (p_2 - p_1)^2 \right) \quad (1) \end{aligned}$$

Similarly

$$\begin{aligned} \text{Var}[Y_1 + Y_2] &= (\sigma^2 + \mu^2)(p_1 + p_2) - \frac{\mu^2}{2} \\ &\quad \times \left((p_1 + p_2)^2 + (q_2 - q_1)^2 \right) \quad (2) \end{aligned}$$

The variance of the more heterogeneous one is less than the variance of the more homogeneous one. In this example heterogeneity is preferable.

To illustrate the last example numerically, assume that $p_1 = p_2 = 1/3$ and $q_1 = 1/6$, $q_2 = 1/2$. Then,

$$\text{Var}[X_1 + X_2] = \frac{2}{3}(\sigma^2 + \mu^2) - \frac{\mu^2}{2} \frac{4}{9} \quad (3)$$

$$\text{Var}[Y_1 + Y_2] = \frac{2}{3}(\sigma^2 + \mu^2) - \frac{\mu^2}{2} \frac{5}{9} \quad (4)$$

In the sequel we will generalize this example to portfolios containing n risks. Throughout the paper bold capital letters denote n -dimensional random vectors, while bold small letters denote n -dimensional vectors with real components. We apply the concepts of majorization and Schur functions to compare the heterogeneity in two portfolios. The comparison is

made for different examples. We assume that the random variables involved in the various examples are statistically independent.

Majorization and Schur Functions

Majorization is a tool to measure the diversity of the components of an n -dimensional vector. Comprehensive references for majorization order and its applications in probability and statistics appear in Marshall and Olkin [3] and Arnold [4].

Conceptually, the vector $\mathbf{y} = (y_1, \dots, y_n)$ majorizes the vector $\mathbf{x} = (x_1, \dots, x_n)$ if the components of $\mathbf{y}$ are more diverse than the components of $\mathbf{x}$. Formally, let $x_{(1,n)} \geq x_{(2,n)} \geq \dots \geq x_{(n,n)}$ and $y_{(1,n)} \geq y_{(2,n)} \geq \dots \geq y_{(n,n)}$ denote the decreasing rearrangement of $\mathbf{x}$ and $\mathbf{y}$; then $\mathbf{y}$ is said to majorize $\mathbf{x}$, denoted as $\mathbf{x} \leq_{\text{maj}} \mathbf{y}$ if

$$\sum_{i=1}^k y_{(i,n)} \geq \sum_{i=1}^k x_{(i,n)}, \quad k = 1, \dots, n-1 \quad (5)$$

and

$$\sum_{i=1}^n y_{(i,n)} = \sum_{i=1}^n x_{(i,n)} \quad (6)$$

Let $1/2 \leq \alpha \leq 1$. Define the $\mathbf{T}$ transform as follows:

$$\begin{aligned} \mathbf{T}\mathbf{x} = \mathbf{T}(x_1, \dots, x_n) &= (x_1, \dots, \alpha x_i \\ &+ (1 - \alpha)x_j, \dots, x_{j-1}, \alpha x_j \\ &+ (1 - \alpha)x_i, \dots, x_n) \end{aligned} \quad (7)$$

Under the $\mathbf{T}$ transform, two components of the vector $\mathbf{x}$ are replaced by their weighted averages such that their sum is not changed. If $\mathbf{x} \leq_{\text{maj}} \mathbf{y}$, then $\mathbf{x}$ can be derived from $\mathbf{y}$ by a finite number of $\mathbf{T}$ transforms, (cf. Marshall and Olkin [3], Arnold [4], and Ma [5]).

Schur increasing functions are functions that increase in the majorization order. This can be formally stated as follows.

Definition 1 Let $A \subset \mathbb{R}^n$. A function $\phi : A \rightarrow \mathbb{R}$ is said to be Schur increasing (decreasing) if $\phi(\mathbf{x}) \leq (\geq) \phi(\mathbf{y})$ for all $\mathbf{x}, \mathbf{y} \in A$, where $\mathbf{x} \leq_{\text{maj}} \mathbf{y}$.

Note that Schur functions are symmetric, that is, if π is a permutation of the numbers $1, \dots, n$,

then $g(x_1, \dots, x_n) = g(x_{\pi(1)}, \dots, x_{\pi(n)})$. Consider the following examples of Schur increasing and Schur decreasing functions:

1. $g : \mathbb{R}_+^n \rightarrow \mathbb{R}_+$, $g(\mathbf{x}) = \prod_{i=1}^n x_i$ is Schur decreasing.
2. A function $\phi : \mathbb{R}_+^n \rightarrow \mathbb{R}_+$, is convex (concave) if for any $\mathbf{y}, \mathbf{z} \in \mathbb{R}_+^n$ and for $0 \leq \alpha \leq 1$

$$\phi(\alpha \mathbf{y} + (1 - \alpha)\mathbf{z}) \leq (\geq) \alpha \phi(\mathbf{y}) + (1 - \alpha)\phi(\mathbf{z}) \quad (8)$$

Marshall and Olkin [3] showed that if ϕ is symmetric and convex then it is Schur increasing.

3. If g is a univariate convex (concave) function, then $\phi(\mathbf{x}) = \sum_{j=1}^n g(x_j)$ is Schur increasing (decreasing).

In the sequel we require a multivariate extension of the majorization ordering. We say that the vectors $(\bar{\mathbf{w}}_1, \dots, \bar{\mathbf{w}}_r)$ are majorized in the Robin Hood (RH) sense by $(\bar{\mathbf{v}}_1, \dots, \bar{\mathbf{v}}_r)$, written as $(\bar{\mathbf{w}}_1, \dots, \bar{\mathbf{w}}_r) \leq_{\text{RH}} (\bar{\mathbf{v}}_1, \dots, \bar{\mathbf{v}}_r)$, if there exists a finite set of $\mathbf{T}_1, \dots, \mathbf{T}_K$ of $\mathbf{T}$ transforms, such that $\bar{\mathbf{w}}_i = \mathbf{T}_1 \dots \mathbf{T}_K \bar{\mathbf{v}}_i$, for $i = 1, \dots, r$. If the components of $\bar{\mathbf{w}}_i$ and $\bar{\mathbf{v}}_i$ are arranged in increasing order and the set of the $\mathbf{T}$ transforms preserve that ordering, we say that $(\bar{\mathbf{w}}_1, \dots, \bar{\mathbf{w}}_r)$ are majorized in the ordered Robin Hood (ORH) sense by $(\bar{\mathbf{v}}_1, \dots, \bar{\mathbf{v}}_r)$, written as $(\bar{\mathbf{w}}_1, \dots, \bar{\mathbf{w}}_r) \leq_{\text{ORH}} (\bar{\mathbf{v}}_1, \dots, \bar{\mathbf{v}}_r)$. In both definitions $\bar{\mathbf{w}}_i$ is obtained from $\bar{\mathbf{v}}_i$ by the same averaging scheme, for all $i = 1, \dots, r$.

For example, the vectors $((1, 3, 11), (1, 2, 5))$ are bigger than $((6, 3, 6), (3, 2, 3))$ in the sense of RH, but not in the sense of ORH. Clearly ORH ordering implies RH ordering.

Heterogeneity in General Insurance Portfolios

We compare two portfolios: portfolio I containing n risks $(X_1, \dots, X_n)$ and portfolio II containing n risks $(Y_1, \dots, Y_n)$. Assume that $X_i = \sum_{j=1}^{N_i} C_{i,j}$ and $Y_i = \sum_{j=1}^{M_i} D_{i,j}$. Thus, N_i or M_i is the number of claims in a certain period for insured i , or business i , and $C_{i,j}$ or $D_{i,j}$ is the j th claim amount of the i th insured, or the i th business line.

In the sequel we will assume that the claim amount distributions of $C_{i,j}$ and $D_{i,j}$ belong to one of the following parametric family of distributions:

C1: Location-scale family

Let $Z_{i,j}$, $i = 1, \dots, n$, $j \geq 1$ be i.i.d. random variables. Let the claim amount in portfolio I be $C_{i,j}$, where $C_{i,j} = a_i Z_{i,j} + s_i$, and let the claim amount in portfolio II be $D_{i,j} = b_i Z_{i,j} + t_i$. We compare the two sets of vectors $(\mathbf{a}, \mathbf{s})$ and $(\mathbf{b}, \mathbf{t})$ by the RH or by the ORH ordering.

Example 1 Let $Z_{i,j}$ be standard normal random variables, and let $\mathbf{a} = (1.5, 1.5, 1.5)$, $\mathbf{s} = (30, 30, 30)$, $\mathbf{b} = ((0.5, 1, 3)$, and $\mathbf{t} = (10, 20, 60))$. Note that

$$\begin{aligned} ((0.5, 1, 3), (10, 20, 60)) &\succeq_{\text{orh}} ((0.5, 2, 2), (10, 40, 40)) \\ &\succeq_{\text{orh}} ((1, 1.5, 2), (20, 30, 40)) \\ &\succeq_{\text{orh}} ((1.5, 1.5, 1.5), \\ &\quad (30, 30, 30)) \end{aligned} \quad (9)$$

Thus, $(\mathbf{a}, \mathbf{s})$ is majorized by $(\mathbf{b}, \mathbf{t})$ in ORH ordering, and hence in RH ordering.

C2: Semigroup property with respect to convolution

$C_{i,j}$ and $D_{i,j}$, $j \geq 1$ are distributed as Z_{θ_i} and Z_{η_i} with distribution functions F_{θ_i} and F_{η_i} , respectively, belonging to the same parametric family of distributions $\mathcal{F} = \{F_\alpha, \alpha \in \Theta\}$. This family has the following property: if Z_α and Z_β are independent with distribution functions F_α and F_β respectively, then $Z_\alpha + Z_\beta$ is distributed as $Z_{\alpha+\beta}$. This property is called the *semigroup property* with respect to convolution. Assume that the vector of parameters for portfolio II is more heterogeneous than that of portfolio I, i.e., $\boldsymbol{\theta} \preceq_{\text{maj}} \boldsymbol{\eta}$.

In Example 2 we present a family of distributions for which assumption C2 holds.

Example 2 Consider the family of gamma distributions with an identical scale parameter, say λ , and shape parameter θ_i or η_i . Thus, the density function of C_i is $f_{C_i}(x) = \frac{1}{\Gamma(\theta_i)} e^{-\lambda x} \lambda^{\theta_i} x^{\theta_i-1}$, and the density function of D_i is the same with the parameter η_i replacing θ_i . Consider two portfolios containing three risks. Let $\lambda = 0.1$, $\boldsymbol{\eta} = (1, 2, 6)$, and $\boldsymbol{\theta} = (3, 3, 3)$. Then

$$(1, 2, 6) \succeq_{\text{maj}} (1, 4, 4) \succeq_{\text{maj}} (2, 3, 4) \succeq_{\text{maj}} (3, 3, 3) \quad (10)$$

When comparing portfolios I and II we consider three types of heterogeneity: (a) heterogeneity in the claims arrival process, (b) heterogeneity in the claim

amounts, and (c) heterogeneity in both the arrival process and the claim amounts.

We consider the individual risk model first and then the collective risk model.

Heterogeneity in the Individual Risk Model

In this case N_i is 1 with probability p_i and 0 otherwise; similarly, M_i is 1 with probability q_i and 0 otherwise. Thus, $X_i = J_{p_i} C_i$, where J_{p_i} equals 1 if individual i has a claim during a given period and 0 otherwise; similarly, $Y_i = K_{q_i} D_i$, with K_{q_i} equals 1 with probability q_i and 0 otherwise. Given that a claim has occurred, its amount is a positive random variable C_i or D_i for the i th insured in portfolio I or II, respectively.

Case a: Heterogeneity in claim occurrence probabilities

We generalize the example given in the introduction to a portfolio containing n risks. Assume that (a) C_i and the D_i , $i = 1, \dots, n$, are i.i.d. random variables. Thus, all the claim amounts are statistically identical. (b) The claim occurrence probabilities $\mathbf{p} = (p_1, \dots, p_n)$ of portfolio I vector is less heterogeneous than $\mathbf{q} = (q_1, \dots, q_n)$ – the claim occurrence probabilities vector of portfolio II in the sense of majorization ordering, i.e., $\mathbf{p} \preceq_{\text{maj}} \mathbf{q}$.

Ma [5] proved that, for any convex function g , $\mathbb{E}[g(\sum_{i=1}^n X_i)] \leq \mathbb{E}[g(\sum_{i=1}^n Y_i)]$. Thus, the more heterogeneous the vector of the claim occurrence probabilities is, the less risky is the portfolio with respect to a convex risk measure. Note that $\mathbb{E}[\sum_{i=1}^n X_i] = \mathbb{E}[\sum_{i=1}^n Y_i]$. Thus $\text{Var}[\sum_{i=1}^n X_i] \leq \text{Var}[\sum_{i=1}^n Y_i]$.

An extension of this result to the case where the claim amounts are not identically distributed can be found in Denuit and Frostig [1].

Case b: Heterogeneity in the Claim Amounts

Assume that portfolios I and II have the same occurrence probabilities. Thus, $X_i = J_{p_i} C_i$ and $Y_i = J_{p_i} D_i$. Further $p_1 \leq p_2 \leq \dots \leq p_n$. Then if

1. assumption C1 holds, i.e., C_i and D_i belong to the same location-scale family of distributions with $(\mathbf{a}, \mathbf{s}) \preceq_{\text{ORH}} (\mathbf{b}, \mathbf{t})$, or,
2. C_i and D_i belong to the same parametric family of distributions with the semigroup property with

respect to convolution, as described in C2, and $\theta \preceq_{\text{ORH}} \eta$,

then portfolio II is riskier than portfolio I, in the sense that for every increasing convex function g the following holds:

$$\mathbb{E} \left[g \left(\sum_{i=1}^n X_i \right) \right] \leq \mathbb{E} \left[g \left(\sum_{i=1}^n Y_i \right) \right] \quad (11)$$

Example 3 Consider two portfolios I and II with the same claim occurrence probabilities $\mathbf{p} = (0.1, 0.2, 0.3)$ and the claim size distributions as described in Example 1 or Example 2. Then portfolio II is riskier than portfolio I in the sense that inequality (11) holds for any increasing convex function.

Case c: Heterogeneity in both the claim occurrence probabilities and the claim amounts

Let the distribution functions of C_i and D_i , $i = 1, \dots, n$ belong to the same location-scale family, i.e., C1 holds, and,

$$(\mathbf{a}, \mathbf{s}, \mathbf{q}) \preceq_{\text{RH}} (\mathbf{b}, \mathbf{t}, \mathbf{p}) \quad (12)$$

Then equation (11) holds for any convex function g . Thus, the risk increases as the heterogeneity of the occurrence probability decreases, and the heterogeneity in the claim amounts distributions increases. In this case, $\mathbb{E} [\sum_{i=1}^n X_i] = \mathbb{E} [\sum_{i=1}^n Y_i]$, while $\text{Var} [\sum_{i=1}^n X_i] \leq \text{Var} [\sum_{i=1}^n Y_i]$. For illustration consider the following example:

Example 4 Consider claim size distributions as per Example 1, and let the claim occurrence probabilities for portfolio I be $\mathbf{p} = (0.1, 0.1, 0.7)$ and for portfolio II be $\mathbf{q} = (0.3, 0.3, 0.3)$. Note that $(\mathbf{a}, \mathbf{s}, \mathbf{q}) \preceq_{\text{RH}} (\mathbf{b}, \mathbf{t}, \mathbf{p})$, since

$$\begin{aligned} & ((0.5, 1, 3), (10, 20, 60), (0.1, 0.1, 0.7)) \\ & \succeq_{\text{RH}} ((0.5, 2, 2), (10, 40, 40), (0.1, 0.4, 0.4)) \\ & \succeq_{\text{RH}} ((1, 1.5, 2), (20, 30, 40), (0.2, 0.3, 0.4)) \\ & \succeq_{\text{RH}} ((1.5, 1.5, 1.5), (30, 30, 30), (0.3, 0.3, 0.3)) \end{aligned} \quad (13)$$

In this example, $\mathbb{E}(X_1 + X_2 + X_3) = \mathbb{E}(Y_1 + Y_2 + Y_3) = 27$, while $\text{Var}(X_1 + X_2 + X_3) = 83.025 < \text{Var}(Y_1 + Y_2 + Y_3) = 504.075$.

Thus, portfolio II is riskier than portfolio I. Contrary to the results that show that the risk decreases

as the heterogeneity in the occurrence probabilities increases, increasing the heterogeneity of some functions of the occurrence probabilities might increase the risk of the portfolio.

Let $\mathbf{h}(\mathbf{p}) = (h(p_1), \dots, h(p_n))$, and $\mathbf{h}(\mathbf{q}) = (h(q_1), \dots, h(q_n))$. Assume that the claim amount distributions belong to a parametric family of distributions with the semigroup property with respect to convolution, as described in assumption C2. Let $h(x) = \ln(x)$, or for $h(x) = \frac{1-x}{x}$, Denuit and Frostig [1] showed that

$$(\mathbf{h}(\mathbf{p}), \theta) \preceq_{\text{ORH}} (\mathbf{h}(\mathbf{q}), \eta) \text{ implies that } \mathbb{E} \left[g \left(\sum_{i=1}^n X_i \right) \right] \leq \mathbb{E} \left[g \left(\sum_{i=1}^n Y_i \right) \right] \quad (14)$$

for any nondecreasing convex function g . Thus, the more heterogeneous portfolio is the riskier one with respect to increasing convex risk measure. Consider the following example for the case where $h(x) = \ln(x)$.

Example 5 Consider portfolio I with claim occurrence probabilities with $\ln(\mathbf{p}) = (-1, -1, -1)$, (corresponding to the vector of occurrence probabilities $\mathbf{p} = (0.3679, 0.3679, 0.3679)$), and portfolio II containing three risks with claim occurrence probabilities with $\ln(\mathbf{q}) = (-2, -0.9, -0.1)$, (corresponding to the vector of occurrence probabilities $\mathbf{p} = (0.1353, 0.4066, 0.9048)$). The claim amount distributions corresponding to portfolios I and II are as per Example 2, i.e., all the claim amounts are gamma distributed with scale parameter 0.1, and shape parameter $\theta = (3, 3, 3)$ for portfolio I, and $\eta = (1, 2, 6)$ for portfolio II. Note that

$$\begin{aligned} & ((-2, -0.9, -0.1), (1, 2, 6)) \\ & \succeq_{\text{ORH}} ((-2, -0.5, -0.5), (1, 4, 4)) \\ & \succeq_{\text{ORH}} ((-1.5, -1, -0.5), (2, 3, 4)) \\ & \succeq_{\text{ORH}} ((-1, -1, -1), (3, 3, 3)) \end{aligned} \quad (15)$$

Thus, $(\ln(\mathbf{p}), \theta) \preceq_{\text{ORH}} (\ln(\mathbf{q}), \eta)$, and portfolio II is riskier than portfolio I.

Heterogeneity in the Collective Risk Model

In this case, N_i and M_i are independent nonnegative integer-valued random variables. N_i or M_i are the number of claim arrivals of business line i during a

certain period for portfolios I and II, respectively. Consider three cases: 1. heterogeneity only in the arrival process, 2. heterogeneity only in the distribution of the claim amounts, and 3. heterogeneity both in the arrival process and claim amounts.

Case 1: Heterogeneity only in the arrival process

Assume the following:

1. The number of type i claim arrivals to portfolios I and II have distribution functions G_{λ_i} and G_{v_i} , respectively, belonging to the same family of parametric distributions $\mathcal{G} = \{G_\lambda, \lambda \in \Lambda\}$, with the semigroup property with respect to convolution. Let $\lambda = (\lambda_1, \dots, \lambda_n)$ and $v = (v_1, \dots, v_n)$.
2. $\lambda \preceq_{\text{maj}} v$ (16)

Then for any symmetric convex function g ,

$$\mathbb{E}[g(\mathbf{X})] \leq \mathbb{E}[g(\mathbf{Y})] \quad (17)$$

In particular, for a univariate convex function g , equation (11) holds.

Thus, the portfolio with the more heterogeneous arrival process is the riskier one.

Example 6 Assume that the number of claim arrivals of business i is a Poisson random variable with parameter λ_i for portfolio I, and parameter v_i for portfolio II. The family of Poisson distributions has the semigroup with respect to convolution. Let $\lambda = (300, 300, 300)$ and $v = (100, 100, 700)$. Then $(100, 100, 700) \preceq_{\text{maj}} (100, 400, 400) \preceq_{\text{maj}} (200, 300, 400) \preceq_{\text{maj}} (300, 300, 300)$.

Case 2: Heterogeneity only in the distribution of the claim amounts

Let $X_i = \sum_{j=1}^{N_i} C_{i,j}$ and $Y_i = \sum_{j=1}^{N_i} D_{i,j}$, where N_i are i.i.d. If $C_{i,j}$ and $D_{i,j}$ belong to the same location-scale parameter, as described in assumption C1 with $(\mathbf{a}, \mathbf{s}) \preceq_{\text{RH}} (\mathbf{b}, \mathbf{t})$, then,

$$\mathbb{E} \left[\sum_{i=1}^n g(X_i) \right] \leq \mathbb{E} \left[\sum_{i=1}^n g(Y_i) \right] \quad (18)$$

for any convex function g .

When $C_{i,j}$ and $D_{i,j}$ belong to the same parametric family with the semigroup property with respect to convolution, as described in assumption C2, then equation (18) holds for any convex function g . In addition equation (11) holds for any convex function g .

Case 3: Heterogeneity both in the arrival process and claim amounts

When both the distributions of the number of claim arrivals and the claim amounts have the semigroup property as described in case 1 and assumption C2 respectively, then increasing heterogeneity both in the claim arrival parameters and in the claim amounts parameters increases the sum of the risks.

$(\lambda, \gamma) \preceq_{\text{RH}} (v, \eta)$ implies that for any convex increasing function g ,

$$\mathbb{E} \left[\sum_{i=1}^n g(X_i) \right] \leq \mathbb{E} \left[\sum_{i=1}^n g(Y_i) \right] \quad (19)$$

The results for the collective risk model yield that heterogeneity either in the claim amounts or in the arrival processes increases risk. For a proof of the results, see Frostig and Denuit [6].

Let $\text{VaR}[X; \alpha] = \inf\{x \in \mathbb{R} | \Pr[X \leq x] \geq \alpha\}$. $\text{VaR}(X)$ is a popular risk measure. Another risk measure that has more desirable properties than the VaR is TVaR , where $\text{TVaR}[X; \alpha] = \frac{1}{1-\alpha} \int_{\alpha}^{\infty} \text{VaR}[X; s] ds$. It can be shown (see Denuit *et al.* [7]) that $\text{TVaR}[X; \alpha] \leq \text{TVaR}[Y; \alpha]$ if and only if $\mathbb{E}[g(X)] \leq \mathbb{E}[g(Y)]$ for any nondecreasing convex function g .

Thus, as the vector of the parameters of the claim amount distributions is more heterogeneous, the portfolio becomes riskier in the individual model and in the collective risk model. Increasing the heterogeneity in the arrival process parameters increases the risk in the collective risk model; however, it decreases the risk in the individual risk model.

Heterogeneity in Life Insurance Portfolios

Unobserved heterogeneity in life insurance portfolios holds for a group of insured individuals with different backgrounds. Thus, different subgroups might have different survival life distributions. In this section we study the impact of this heterogeneity on the premium. Spreeuw [8] considered a portfolio with n contracts, $n \geq 2$ for one period, say a year. Let p_r be the probability that insured r survives after 1 year. Assume that all insureds pay the same premium $\Pi = \Pi(\mathbf{p})$ at the beginning of the period. At the end of the period a proportion δ of the mortality profit or loss is allocated to those who survived the period. Let D be the amount paid at the end of the period by

the insurer to the insured upon death. Assumption of zero expected loss implies that the premium $\Pi(\mathbf{p})$ is

$$\Pi(\mathbf{p}) = D \left(1 - \frac{(1 - \delta) \sum_{m=1}^n p_m}{n \left[1 - \delta \left[1 - \prod_{m=1}^n (1 - p_m) \right] \right]} \right) \quad (20)$$

Since $\prod_{j=1}^n (1 - p_j)$ is Schur decreasing, $\Pi(\mathbf{p})$ is also Schur decreasing. Then consider another portfolio with survival vector $\mathbf{q}$, where $\mathbf{q} \leq_{\text{maj}} \mathbf{p}$ implies that $\Pi(\mathbf{q}) \geq \Pi(\mathbf{p})$. Especially if $\bar{p} = \frac{1}{n} \sum_{i=1}^n p_i$ and $\bar{\mathbf{p}} = (\bar{p}, \dots, \bar{p})$, then $\Pi(\bar{\mathbf{p}}) \geq \Pi(\mathbf{p})$.

Thus, in the Spreuw model the premium decreases as the portfolio's heterogeneity increases. Hence, the hidden heterogeneity causes the insurer to overestimate the premium.

Similar results were obtained by Dahan *et al.* [9, 10]. They considered a heterogeneous portfolio with n contracts, $n \geq 2$, with survival probabilities as in the Spreuw model. A common death benefit D is paid at time $(k+1)/l$ if the insured dies in the interval $(k/l, (k+1)/l)$, $k = 0, \dots, l-1$, and survival benefit S is paid at the end of the year. The life pays a premium $\pi(\mathbf{p})$ at k/l as long as he is alive. Let ${}_t p_r$ be the probability that the r th insured survives up to age $x+t$. Let $f(\mathbf{p}) = \sum_{r=1}^n p_r$, and $g(\mathbf{p}) = \sum_{k=0}^{l-1} \sum_{r=1}^n (k/l) p_r \tilde{v}^k$, where $\tilde{v} = (1+i)^{-1/l}$, and i is the annual interest rate. The equation of value yields

$$\pi(\mathbf{p}) = -(1 - \tilde{v})Dg(\mathbf{p}) + \frac{m \cdot D + \tilde{v}^l \cdot (S - D) \cdot f(\mathbf{p})}{g(\mathbf{p})} \quad (21)$$

In order to calculate the premium one needs to estimate ${}_t p_r$, for $0 \leq t \leq 1$. The most known approximations in the actuarial literature are

1. Exponential approximation: ${}_t p_r = (p_r)^t$
2. Balducci approximation: ${}_t p_r = \frac{p_r}{(1-t)p_r + t}$
3. linear approximation: $1 - {}_t p_r = t(1 - p_r)$.

Under the exponential or Balducci approximations, ${}_t p_r$ is a concave function of p_r , while under the linear approximation, ${}_t p_r$ is linear in p_r and therefore both convex and concave. Since the sum of Schur decreasing functions is Schur decreasing, the function $g(\mathbf{p})$ is Schur decreasing. Therefore, assuming

the exponential or the Balducci approximations, equation (21) yields that the premium is Schur increasing in $\mathbf{p}$. Thus, the more heterogeneous the population (in the sense of majorization ordering), the higher the premium. When applying the linear approximation, the premium is unaffected by the heterogeneity (in the majorization ordering sense). Under different types of approximations presented by Jones and Mereu [11], and Dahan *et al.* [10] arrived at the opposite conclusion.

Dahan *et al.* [12] considered a portfolio containing n endowment insurance contracts issued for M years. They assumed that all insureds are at the same age at the policy issue time and that their survival probabilities belong to a parametric family of survival functions. Under some conditions on the force of mortality, they showed that as heterogeneity increases the premium increases. Thus, assuming homogeneous portfolio the insurer underestimates the premium. Dahan *et al.* [13] also studied the case of n endowment insurance contracts issued for M years, where the insureds are subject to the same mortality table but are at different ages at the policy issue date. In this case also, the premium increases as the heterogeneity of the insureds' ages increases.

Conclusion

We have demonstrated that heterogeneity in the distribution functions of the risks influence the risk measure of the corresponding portfolios. However, to see whether heterogeneity increases or decreases risk, one has to check the type and the source of heterogeneity. In the individual and collective risk models, we saw that heterogeneity in the claim amounts increases any nondecreasing convex risk measure. In the collective risk model, heterogeneity in the claim arrival process also increases risk. The contrary happens when increasing heterogeneity in the claim occurrence probabilities in the individual model.

As for life insurance portfolios, we saw that ignoring heterogeneity might cause the insurer to overestimate or underestimate the premium depending on the type and the source of increases in heterogeneity.

Inferiority and Superiority Trials

A superiority clinical trial (*see Randomized Controlled Trials*) is often conducted to establish that an experimental treatment (e.g., a therapy, preventive agent, or medical device) is superior to a control treatment (e.g., an accepted “standard” treatment, or a placebo), by some measure of treatment effect or *efficacy*. A noninferiority clinical trial is typically conducted to establish that the treatment effect of an experimental treatment is not much worse than that of an accepted “standard” treatment or an active-control treatment [1]. When an experimental treatment is anticipated to be nearly as effective as an active-control treatment, it might be worth developing if it has other advantages such as reduced *toxicity* and/or cost. An equivalence trial (a two-way noninferiority trial) can be used to establish that an experimental treatment is neither much better nor much worse than an active-control treatment [1].

Superiority and noninferiority clinical trials are often conducted as *Phase III comparative clinical trials*. In these trials, subjects that meet the study criteria are recruited and often assigned to either the experimental treatment arm or the control treatment arm using *randomization* procedures. Sometimes, *blinding* or *masking* is implemented to ensure that the participating patients or both the participating patients and their physicians are unaware of the *treatment allocation* as it can have a strong effect on the observed treatment outcome. It is important to select appropriate randomization procedures and/or blinding methods in order to minimize the risk of leading to some kind of *bias in clinical research*.

Superiority Trials

A prominent example of a superiority trial is the Salk vaccine trial of 1954. This trial was conducted to assess the effectiveness of the Salk vaccine as a protection against paralysis or death from poliomyelitis as described in more detail by Meier [2]. In one part of this study, 401 973 children were randomly assigned to either a treatment arm injected with Salk vaccine or a placebo arm injected with a salt solution. The trial was double blind, that is, neither the

children nor the diagnosing physicians were aware of who had been given the Salk vaccine or the salt solution.

When designing such superiority clinical trials, one must guard against the risk of committing any of the two common types of errors in typical hypothesis-testing-based trial designs. A type I error is made if the study leads to a false conclusion that the experimental treatment is superior to the control and a type II error is made if the study fails to establish superiority when the experimental treatment is indeed superior in efficacy. The probabilities of type I and type II errors are often denoted as α and β , respectively. When a trial is designed with the proportion of events (e.g., the proportion of deaths in Salk vaccine trial) as the primary efficacy *endpoint*, the investigators often have some idea of the order of magnitude of the proportions they are studying. A difference $\Delta = p_E - p_C$, between the projected proportion of events p_E for the experiment treatment and p_C for the control treatment, that is worth detecting is often specified [3]. The required sample size (i.e., number of subjects needed) for the study to ensure desired power $(1 - \beta)$ for detecting a specified difference Δ among the two treatment arms, at a prespecified significance level α (or type I error), using a one-sided z -test, can be obtained as

$$n_C = \frac{\left\{ z_\alpha \sqrt{\bar{p}\bar{q}} \left(1 + \frac{1}{k} \right) + z_\beta \sqrt{p_C q_C + \frac{p_E q_E}{k}} \right\}^2}{(p_E - p_C)^2},$$

$$n_E = k n_C \quad (1)$$

where the sample size (n_E) for the experimental treatment arm is k times as large as the sample size (n_C) for the control arm, $q_C = 1 - p_C$, $q_E = 1 - p_E$, $\bar{p} = (p_C + k p_E)/(1 + k)$, $\bar{q} = 1 - \bar{p}$, and z_α and z_β are the upper percentiles of the standard normal distribution corresponding to α and β [4]. More details on superiority trial design and sample-size formulas with various efficacy endpoints can be found in Piantadosi [5] and Chow and Liu [6].

Frequently, a formal hypothesis test is conducted to assess if superiority is met on the basis of data from the superiority trial. In practice, a two-sided test is often recommended even though the investigators are only interested in a one-sided alternative hypothesis [3]. The true value of the efficacy parameter can be

estimated and the corresponding confidence interval obtained for each treatment arm. The magnitude of the efficacy differences among treatment groups can be evaluated using appropriate measures such as, difference in response rates, means, hazard rates, median survival times, etc., along with corresponding confidence intervals [3–6].

Recent advances in medical science have lead to effective treatments for many diseases. Thus, superiority trials are often required to compare experimental treatment to an existing effective treatment instead of a placebo. Much effort is also being devoted to conducting noninferiority trials for developing experimental treatment which, without being necessarily more effective than the standard treatment, can have other important advantages such as in reducing *toxicity* (see **Toxicity (Adverse Events)**) and/or cost, which is discussed next.

Noninferiority Trials

In a noninferiority clinical trial, it is common to specify a threshold for the margin of indifference when comparing the treatment effects between the experimental treatment and the control treatment [1]. For example, when comparing the proportion of success in the experimental treatment (P_E) with that of the control treatment (P_C), the noninferiority margin (or the margin of indifference), δ , is often defined as the maximum difference amount by which the experimental treatment is not considered clinically much worse than the control treatment if $P_E > P_C - \delta$. The noninferiority margin δ , should be prespecified and determined on the basis of clinical judgment [1, 7, 8].

One must guard against the risk of committing any of the two types of errors in typical hypothesis-testing-based noninferiority trial designs [8]. A type I error is made if the experimental treatment is falsely concluded as noninferior to the control. A type II error is made if one fails to conclude noninferiority when the experimental treatment is indeed noninferior compared to the control treatment. For a prespecified noninferiority margin δ , one can determine the sample size (the number of subjects) needed to ensure desired type I and II errors as discussed in Farrington and Manning [9], and Chow and Liu [6], among others.

Frequently, a hypothesis test is performed to assess if noninferiority is met. For example, when efficacy is

in terms of proportion of successes, one may perform a z -test with the following test statistic,

$$T_n = \frac{p_E - p_C + \delta}{\sqrt{\frac{\hat{P}_E(1 - \hat{P}_E)}{n} + \frac{\hat{P}_C(1 - \hat{P}_C)}{n}}} \quad (2)$$

where δ is the noninferiority margin, p_C and p_E are the observed efficacy proportions and $\hat{P}_C$ and $\hat{P}_E$ are the maximum-likelihood estimates of the efficacy proportion in the control and experimental treatment arms, respectively [6, 9]. Noninferiority can be claimed by comparing the observed value of T_n to the percentiles of the standard normal distribution. The magnitude of the efficacy difference between the treatment arms can be evaluated using appropriate measures such as, difference in response rates, means, hazard rates, median survival time, along with the corresponding confidence intervals [6, 9].

Noninferiority trials are frequently conducted to develop less toxic and/or less costly new treatments compared to an accepted active-control treatment. Thus, the active control should truly be effective. Otherwise, a treatment that is worse than placebo may be approved on the basis of the results of a noninferiority test. Furthermore, noninferiority trials often need a large sample size, thus are costly and may require many years to be completed. Therefore, it is important that the trial not only studies an experimental treatment, which offers meaningful advantages over the standard control, but also is feasible and can be completed in a timely fashion. Finally, proper *monitoring* of such trials is important to minimize the risk in denying patients an effective standard treatment.

Influence Diagrams

Influence diagrams (IDs) are a very useful tool for representing decision problems, especially when the problems exhibit considerable symmetry. Unlike the decision tree (*see* **Decision Trees**), whose topology represents relationships between events and particular decisions taken, the ID represents relationships between measurement and state *random variables* and *decision variables*. Consequently, IDs exhibit the following characteristics:

- They typically have a topology that is much more compact than, for example, the decision tree – there usually being far fewer variables in a problem than events and decisions.
- They represent qualitative information that can be elicited from assertions in common language and do not need early specifications from the client of numerical values.
- Unlike the decision tree, they can express independencies between random variables in the description of a problem;
- Like the decision tree, they can be used as a framework for neatly encoding quantitative information about the decision process so that Bayes decision rules (*see* **Decision Modeling**) can be calculated.
- They can represent continuous, discrete, or mixtures of continuous and discrete problems equally well.

The nodes of an ID represent decision variables, measurement and state random variables, and utility functions, while the existence of a directed edge or arrow from one node N to another M suggests that the value of N might influence the value of M . A simple example of an ID is given in Figure 1. An experiment is performed, giving a realization $X = x$ before an action $a \in A$ need be taken. The decision maker (DM) has a utility function that is a function of a consequence C and a only. The prior distribution of C and the conditional distribution of $X|C$ have both been elicited from the DM. The value of C is not determined before the action a is taken.

Conventionally, actions are associated with a decision node $\square$, random variables by a node $\circ$, and utility functions by a node $\diamond$. The dependence of X on C is depicted by the arrow from C to X . Because

a can only be chosen as a function of X and not C , there is an arrow from X to a but not one from C to a . Finally, because U is a function of a and C but not X , there is an arrow from a to U and from C to U , but not from X to U . A formal definition of this construction is given below.

Note that unlike the decision tree, the ID is very compact. This is because, unlike the decision tree, it does not represent the state space of variables associated with the nodes in the graph. It does represent *dependencies* or influences between the nodes. These dependence relationships can be elicited directly and are valuable for interrogating model plausibility (*see* below) and for determining simple subclasses of optimal decision rules (*see* [1, 2]). They provide a useful framework around which efficiently optimal decision rules can be calculated.

The genesis of IDs was a rather complicated one. Bayes nets (BNs), which represent various dependence relationships between random variables (but not actions or utility functions), by directed acyclic graphs (DAG) were being studied with some vigor, first by mathematical biologists and then by statisticians, by the 1980s [3, 4]. Meanwhile, several researchers in Artificial Intelligence, including Pearl, had developed similar graphical tools for representing dependence structures (*see* [5] for references). Parallel to this, decision analysts developed IDs to represent decision problems [6]. Pioneering work by Shachter [7] noted the connection between the two fields – where the BN could be seen as a special case of an ID having no decision or utility nodes – since when the field has become very cross disciplinary. Increasingly fast computational algorithms have been developed for BNs over the last 20 years. Many such algorithms have been implemented in code and these are now adapted to decision problems as well as inference problems (*see*, for example [8, 9]).

In this article, rather than describing the technical features of fast algorithms for easy calculation of Bayes decision rules, which is probably not central to the interests of this audience and is well documented elsewhere [1, 8–10], the focus is on the use of IDs for *problem representation*. Of course, once a problem has been faithfully represented as an ID, the algorithms mentioned above can be implemented and calculations made.

Partly because of the cross disciplinary nature of their development, the semantics of IDs is still not fully agreed upon. Here, we most closely follow the

Figure 1 A simple influence diagram

notation of Shachter. It is simplest to first consider the BN (sometimes also called the *Bayesian network*, the *chance influence diagram*, or *probability directed acyclic graph* (DAG)) and only after this, the ID itself.

Irrelevance and Conditional Independence

One key element of any qualitative description of a problem is whether two uncertain measurements X and Y are related. Only if they are related to one another is it necessary to quantify *how* they are related. If learning the value of X is irrelevant to predictions of Y , then this can be expressed probabilistically by stating that the probability density or mass function $p_{X,Y}(x, y) = p_X(x)p_Y(y)$, where $p_X(x)$ is the marginal mass function of X and $p_Y(y)$ is the marginal density/mass function of Y . Note that from this observation we can make the deduction that if X is irrelevant to predictions of Y then, by the symmetry of the relation above, Y must be irrelevant to predictions about X – a deduction not immediately apparent from the statements in common language.

Independence is not quite a rich enough concept to be of much practical use. However *conditional* independence is. Furthermore, like independence, it can also be expressed in common language. Thus, suppose the DM asserts that once she knows the value of Z , whatever that value of Z is, the value of X is then irrelevant to any predictions she might make concerning Y . Then, if she is a Bayesian and therefore thinking probabilistically, we can translate this statement as asserting that Y is independent of X given Z . This, in turn, is equivalent to her asserting that her subjective conditional density or mass

function $p_{Y|Z,X}(y|x, z)$ is not an explicit function of x . We write this conditional independence assertion as $Y \perp\!\!\!\perp X|Z$.

It is easily shown that if $Y \perp\!\!\!\perp X|Z$ and if $p_{X,Y,Z}(x, y, z)$ is the joint density/mass function of (X, Y, Z) , then

$$p_{X,Y,Z}(x, y, z) = p_{Y|Z}(y|z)p_{X|Z}(x|z)p_Z(z) \quad (1)$$

where $p_{X|Z}(x|z)$, $p_{Y|Z}(y|z)$ are respectively the densities of X given Z and Y given Z , and $p_Z(z)$ is the marginal density/mass function of Z .

Conditional independence has two properties that translate directly into statements about conditions a Bayesian should obey while considering irrelevance. The first is *symmetry*, which is a generalization of the symmetry we observed for independence. Thus, for any three vectors of measurements $(\mathbf{X}, \mathbf{Y}, \mathbf{Z})$ we must have that the statements $\mathbf{Y} \perp\!\!\!\perp \mathbf{X}|\mathbf{Z}$ and $\mathbf{X} \perp\!\!\!\perp \mathbf{Y}|\mathbf{Z}$ are equivalent. Thus, if the Bayesian DM states that given the value of $\mathbf{Z}$, $\mathbf{X}$ provides no further useful information about $\mathbf{Y}$, then she also should believe that given the value of $\mathbf{Z}$, $\mathbf{Y}$ provides no further useful information about $\mathbf{X}$.

A second useful *decomposition* property is the following: if $(\mathbf{W}, \mathbf{X}, \mathbf{Y}, \mathbf{Z})$ are random vectors, then the statement $\mathbf{Z} \perp\!\!\!\perp (\mathbf{X}, \mathbf{Y})|\mathbf{W}$, is logically equivalent to the two statements (asserted together) that $\mathbf{Z} \perp\!\!\!\perp \mathbf{Y}|\mathbf{W}$ and $\mathbf{Z} \perp\!\!\!\perp \mathbf{X} |(\mathbf{W}, \mathbf{Y})$. Pearl illustrates why this equivalence should be expected to hold not only for probabilistic systems but also for any reasonable semantics of irrelevance using a simple example. Suppose your current relevant knowledge about $\mathbf{Z}$ is encapsulated in the random vector $\mathbf{W}$. You now read a book in two volumes, which might be informative about $\mathbf{Z}$. Let the information in the first volume be $\mathbf{Y}$ and the information in the second volume be $\mathbf{X}$. The assertion $\mathbf{Z} \perp\!\!\!\perp (\mathbf{X}, \mathbf{Y})|\mathbf{W}$ says that, given what you already know $\mathbf{W}$, the two volumes give no additional information relevant to any predictions about $\mathbf{Z}$. This surely implies that $\mathbf{Z} \perp\!\!\!\perp \mathbf{Y}|\mathbf{W}$ – given what you already know, $\mathbf{W}$, the first volume gives no additional information relevant to any predictions about $\mathbf{Z}$; and also $\mathbf{Z} \perp\!\!\!\perp \mathbf{X} |(\mathbf{W}, \mathbf{Y})$ – given what you already know, $\mathbf{W}$, and the information in the first volume, the second volume gives no additional information relevant to any predictions about $\mathbf{Z}$. Conversely, if either one of $\mathbf{Z} \perp\!\!\!\perp \mathbf{Y}|\mathbf{W}$ and $\mathbf{Z} \perp\!\!\!\perp \mathbf{X} |(\mathbf{W}, \mathbf{Y})$ is not true, then surely the DM must believe that the pair of volumes, taken together, have some relevant information about $\mathbf{Z}$, additional to $\mathbf{W}$.

The point is, then, that qualitative dependence relations made by a Bayesian DM must obey certain rules (the ones described above are called the *semigraphoid axioms* [5, 11, 12]). If elicited statements do not obey these rules, then they are self contradictory. The analyst then needs to help the DM to explore the reasons for these apparent contradictions and help her develop her model so that these contradictions disappear. One big practical problem is how the analyst can converse with the DM in such a way that she can fully engage in the development of the model. Only then can she take ownership of the resulting model. For example, she may well be scared off by the sort of notation used above. There is a way of doing this when the model describes the outworkings of a process – the BN. On the one hand, this graph depicts the process in an entirely natural way; however on the other, it is an entirely formal construction and so supports logical interrogation.

Representing Dependencies Using a Bayes Net

For simplicity, assume that our problem has a discrete formulation and let the n variables of interest be denoted by $\mathbf{X} = (X_1, X_2, \dots, X_n)$, these having a joint probability mass function $p(\mathbf{x})$. Then the usual rules of probability tell us that we can calculate

$$p(\mathbf{x}) = p_1(x_1)p_2(x_2|x_1)p_3(x_3|x_1, x_2) \dots \times p_n(x_n|x_1, \dots, x_{n-1}) \quad (2)$$

Suppose that the ordering of these variables follows the natural development of the process in the sense that the events measured by X_j do not happen after those measured by X_i if $j < i$. Quite often, the DM may be initially hesitant about specifying a functional form for $p_i(x_i|x_1, \dots, x_{i-1})$ in this formula. However, she is often quite happy that, for each X_i , $2 \leq i \leq n$, given the values of the subset $Q_i(\mathbf{X})$ – called the *parents* of X_i – of the variables $\{X_1, \dots, X_{i-1}\}$ listed before X_i , the values of the remaining variables $R_i(\mathbf{X})$ listed before X_i are irrelevant for forecasting X_i . In the notation of the last section, this simply states that

$$X_i \perp\!\!\!\perp R_i(\mathbf{X}) \mid Q_i(\mathbf{X}) \quad (3)$$

where

$$Q_i(\mathbf{X}) \subseteq \{X_1, \dots, X_{i-1}\} \quad (4)$$

$$R_i(\mathbf{X}) = \{X_1, \dots, X_{i-1}\} \setminus Q_i(\mathbf{X}) \quad (5)$$

In terms of the probability breakdown, when $X_i \perp\!\!\!\perp R_i(\mathbf{X}) \mid Q_i(\mathbf{X})$, this tells us that $p_i(x_i|x_1, \dots, x_{i-1})$ can be written as an explicit function of $(x_i, Q_i(\mathbf{x}))$.

This set of statements about the relationships between $\{X_1, X_2, \dots, X_n\}$ can now be written as a DAG, G . The vertices or nodes of this graph are labeled by the set $\{X_1, \dots, X_n\}$ of variables describing the problem. We connect a directed edge from $X_j \rightarrow X_i$ if and only if X_j is a *parent* of X_i , that is $X_j \in Q_i(\mathbf{X})$. Notice the simplicity of this representation: a variable remains unattached to X_i only if it does not provide its own unique useful information, which adds to that given by the parents of X_i .

1. A BN is said to be *valid* if all the irrelevance statements (equation 3) that can be read in its DAG are believed by the DM.
2. A DAG of a BN is always acyclic because, by definition, parents are listed before children. Note that there are (albeit less powerful) analogous potentially cyclic graphs (e.g. [13]) that relate to simultaneous equation models.
3. It is important to realize that it is the *missing* edges in a DAG G of a BN that are significant. In particular, the DAG where all nodes are connected to each other is completely uninformative about the irrelevance relationships between its variables.
4. The *d*-separation theorem – first proved by Verma and Pearl [5, 9, 11, 14] – allows for *all* valid deductions to be read directly off the DAG. It relies only on the graphoid properties discussed above. This result enables the DAG of a BN to be used to query whether a given irrelevance statement of the form $\mathbf{Y} \perp\!\!\!\perp \mathbf{X} \mid \mathbf{Z}$, where $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ are subsets of the variables of the problem – as represented as vertices of G – can be logically deduced from the DM's original irrelevance statements. This is very useful because the analyst can take the statements given by the DM and confront her with statements that can be logically deduced from what she has said. Only if these deductions look plausible to her can

the model be requisite [15]. If the DM does not believe them, then she should be able to explain why. On the basis of this explanation, the analyst can then support the DM in modifying her BN – see the example below. The modified DAG of the new BN contains either more relationships (edges) or more variables (vertices) than the original. Briefly, to check the validity of $\mathbf{Y} \perp\!\!\!\perp \mathbf{X} | \mathbf{Z}$, where the subsets $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ are all disjoint from one another the analyst acts as follows:

- Takes the subgraph G' of G , whose vertices include only those variables $\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z}$ in the query, together with those other variables – represented as vertices in G – that appear *before* a variable in $\mathbf{X} \cup \mathbf{Y} \cup \mathbf{Z}$ in G . Let there be a directed edge in G' between two of its vertices if and only if that directed edge appears between the corresponding edges in G .
 - Joins each pair of unconnected parents of vertices in G' by an undirected edge to form a new (mixed) graph G'' .
 - Substitutes each directed edge in G'' by an undirected edge to form an undirected graph G''' .
 - If every path in G''' between any vertex X_i in $\mathbf{X}$ and any vertex X_j in $\mathbf{Y}$ passes through some vertex X_k in $\mathbf{Z}$, then it can be deduced that $\mathbf{Y} \perp\!\!\!\perp \mathbf{X} | \mathbf{Z}$, i.e., that the DM implicitly believes that, once the values of variables in $\mathbf{Z}$ are known, the values of variables in $\mathbf{X}$ give no further information relevant to prediction about $\mathbf{Y}$. On the other hand, if there is a path in G''' between an X_i in $\mathbf{X}$ and an X_j in $\mathbf{Y}$ that does not pass through any of the variables in $\mathbf{Z}$, then there is at least one probability distribution consistent with the elicited irrelevance statements such that $\mathbf{Y} \perp\!\!\!\perp \mathbf{X} | \mathbf{Z}$ is not true – i.e., where $\mathbf{X}$ provides further information to $\mathbf{Z}$ about $\mathbf{Y}$. More details of this result, including a proof, can be found in [14], with simpler proofs being available in [11] and [9].
5. The conditional independence structure encoded in G can be used as an efficient framework for storing elicited conditional probabilities, and when there are significant numbers of elicited irrelevances, this framework is usually far more efficient than, for example, the tree. Furthermore, the framework can also often be used to quickly

ensure the fast calculation of margins of interest even in very high dimensional problems, provided the number of parents of all its nodes are small. Details of such algorithms can be found in [9] and [8].

Consider the following grossly simplified but, nevertheless, illuminating example of how eliciting a BN can help the DM express important features of an underlying process that might influence its development.

Example 1 A utility company needs to determine an optimal portfolio of its programs of work. For any promising scheme, the protocol the company produces provides a rough estimate R of the cost of the work. On the basis of this, it may proceed to obtain a more detailed estimate D from its civil engineers. The program is then put out to tender, and the firm placing the lowest bid T receives the work. The work is then completed and the final outturn cost O – which may include any unforeseen costs – is charged. The company needs to monitor its current evaluation of the outturn cost O so that it can appropriately balance financial risks between this and other projects.

The company currently uses the detailed estimate to arrive at the probability distribution of the tender price, and the outturn price is estimated using the winning tender bid T . It follows that they are implicitly assuming that the BN with DAG given in Figure 2 is valid.

To check this model, the analyst can ask two questions related to $T \perp\!\!\!\perp R | D$ and $O \perp\!\!\!\perp (R, D) | T$, respectively, which can be stated in words as follows:

- “Knowing the detailed estimate, can you think of any scenario where also knowing the rough estimate would assist in refining an estimate for the tender price?” and
- “Are there any scenarios in which the detailed or rough estimate might provide additional useful information about the outturn price over and above that provided by the winning tender price?”

Figure 2 An initial DAG for Example 1

When confronted with the second query, it is noted that for projects where the tender price is much less than the detailed estimate, the outturn price is often much higher than would normally be estimated from the tender price. The company can also provide an explanation for why this is so. In periods of economic recession, work is hard for the contractors to find. In such circumstances, it is not unusual for a firm to place a low tender to secure the work and then endeavor to find many “add-ons”, so that the outturn price they finally charge is economic to them.

Note from this example that presenting the company with the BN has provided a qualitative framework from which it has modified its description of the problem: incorporating a new variable E , representing the economic environment into the description. The new BN is now given in Figure 3.

If relevant ways of measuring E can be found, then more reliable estimates of the outturn price based on T and E should be forthcoming. Notice that, using the semigraphoid properties directly, other queries derivable from the d -separation theorem could be fed back and checked for their plausibility. So, for example, the analyst could ask “If you had to resurrect the rough estimate of a project because this had been lost, and you had both your detailed estimate and the tender bid available, then would the detailed estimate alone be sufficient to resurrect the rough estimate as accurately as possible?” This should be so, because the symmetry property demands that – as the DM has asserted above – $T \perp\!\!\!\perp R|D$, then it can be deduced that $R \perp\!\!\!\perp T|D$, i.e., that the answer to the above question is “yes”. However, note that this question is not obviously equivalent to the original assertion. So, other forgotten dependencies might be teased out of the DM just by asking this question. Similarly, to check whether our model now implies $O \perp\!\!\!\perp D|T$, use the transform G to G''' as described above (Figure 4).

Figure 3 A modified BN

Figure 4 Checking independence using a moralized BN

Note that the path (D, E, O) in G''' between D and O is not blocked by T and so we can conclude that, if E is not known for this project, then the detailed estimate D may well be informative about the outturn price O . However, if we have recorded both T and the measure E of the economic environment, then note that (T, E) block all paths between D and O , so under the adapted graph, D is assumed unnecessary to record, if both (T, E) are recorded.

The Semantics of Influence Diagrams

An ID is a generalization of a BN, extended to include both decision variables and utilities. These IDs are useful for coding a particular but common type of decision problem. Such “uniform” problems have two characteristics. First, they can be formulated so that each possible decision rule $d(\mathbf{X}) \in A$ – the set of possible decision rules – can be expressed as a totally ordered sequence of subdecisions $(d_1(\mathbf{X}), d_2(\mathbf{X}), \dots, d_k(\mathbf{X}))$, where $d_j(\mathbf{X}) \in A_j : 1 \leq j \leq k$, and where the DM knows and remembers the decisions $\{d_1, d_2, \dots, d_{j-1}\}$ she has acted out or committed to when she commits to $d_j(\mathbf{X})$, $2 \leq j \leq k$. We assume here that the commitment to any acts $\{d_1, d_2, \dots, d_{j-1}\}$ does not constrain the possible choice $d_j(\mathbf{X}) \in A_j : 2 \leq j \leq k$. Technically, this can be written as the condition that $A = A_1 \times A_2 \times \dots \times A_k$, where the *decisions variables* $d_1(\mathbf{X}), d_2(\mathbf{X}), \dots, d_k(\mathbf{X})$ are allowed to take any value in their range.

The next issue is to code what information is available when one of these decision variables has to be enacted. Order the components of $\mathbf{X}$ so that they are consistent with the order in which they

happen under a particular reference decision rule $d(\mathbf{X}) \in A$. Let $T_1(\mathbf{X}|d(\mathbf{X}))$ denote the set of random variables that is the union of the set $Q'_1(\mathbf{X}|d_1(\mathbf{X}))$ of all the random variables whose values are known before $d_1(\mathbf{X})$ is enacted together with all variables that measure events that have happened before variables in $Q'_1(\mathbf{X}|d_1(\mathbf{X}))$, but are still unknown to the DM when she commits to $d_1(\mathbf{X})$. Similarly for $i = 1, 2, \dots, k$, let $T_i(\mathbf{X}|d(\mathbf{X}))$ denote the union of the set of variables that have happened which contains variables that happen between when $d_j(\mathbf{X})$ is taken and $d_{j-1}(\mathbf{X})$ is taken and $Q'_j(\mathbf{X}|d_j(\mathbf{X}))$, $j = 1, 2, \dots, k$. Finally, let $T_{k+1}(\mathbf{X}|d(\mathbf{X}))$ denote the remainder of the random variables that have not yet appeared as components of $\{T_1(\mathbf{X}|d(\mathbf{X})), \dots, T_k(\mathbf{X}|d(\mathbf{X}))\}$. Thus, $T_{k+1}(\mathbf{X}|d(\mathbf{X}))$ contains a subset of the variables that remain unknown for any decision rule $d(\mathbf{X}) \in A$ and happen after the DM has committed herself to all aspects of the decision process. Our second condition can now be stated. The partition of variables $\{T_i(\mathbf{X}) : 1 \leq i \leq k+1\}$ defined above must not depend on the DM's choice of $d(\mathbf{X}) \in A$ and so satisfies the condition above for *all* possible $d(\mathbf{X}) \in A$ (not just the reference decision). This second condition demands that whatever value a subdecision is set to, it does not disrupt the process in a way that influences the *order* in which the random variables describing the process happen. This order is the same regardless of the decisions taken – although setting subdecision variables to different values may well influence the *value* a subsequently occurring variable takes. Here, we call a decision problem *uniform* when it satisfies the two conditions stated above.

Example 2 A company plans to launch a cosmetic product, but are concerned that one of its constituents might provoke an attributable allergic reaction in some users if its concentration is higher than a currently unknown threshold B . If the company launches the product when it is possibly allergenic, then they will have to withdraw the product with a loss of profit and reputation. However, the higher the concentration of this constituent, the more effective the product and so the higher their predicted sales and also their reputation. They, therefore, plan to perform tests of the constituent. Their first subdecision is the duration l of the experiment. The longer the experiment, the better the quality of information X about the potential to cause an allergic reaction as a function of concentration, but the lesser the profit

from the product, since competing products marketed by others can be expected to appear in the medium term. The second subdecision is the concentration c to use in the final marketed product.

It is easy to check that this is a uniform decision problem in which the number of subdecisions $k = 2$. The danger threshold of the concentration waits to be discovered, so B is our first variable, whilst the second variable X is known before the second subdecision c . So in the notation above, $T_1 = X_1 = B$, $d_1 = l$, $T_2 = X_2 = X$, $d_2 = c$, and T_3 is empty.

Note that, for a uniform decision problem, any decision rule $d(\mathbf{X}) \in A$ can be specified in terms of an ordered sequence of subdecisions $(d_1(\mathbf{X}), d_2(\mathbf{X}), \dots, d_k(\mathbf{X}))$. Furthermore, when the DM commits to an act $d_j(\mathbf{X})$, this will be a function of a subset $Q'_j(\mathbf{X}|d_j(\mathbf{X}))$ of the variables in $X_j \in T^{(j)}(\mathbf{X}) = \bigcup_{i=1}^j T_i(\mathbf{X})$ – the variables known by the time $d_j(\mathbf{X})$ is enacted – together with her acts $d^{(j-1)} = \{d_1, d_2, \dots, d_{j-1}\}$ so far committed to and remembered, $2 \leq j \leq k$. Let

$$Q_j = \bigcup \{Q'_j(\mathbf{X}|d_j(\mathbf{X})) : d(\mathbf{X}) \in A\} \cup \{d_1(d(\mathbf{X})), d_2(d(\mathbf{X})), \dots, d_{j-1}(d(\mathbf{X}))\} \quad (6)$$

and call this set Q_j the *parents* of d_j . The parents of d_j are then simply the set of variables that have been seen and decisions that have been enacted so far, by the time $d_j(\mathbf{X})$ needs to be chosen.

Fortunately, a decision problem is often uniform. When this is so, it is possible to represent many of its qualitative features by drawing a very evocative and useful graph, similar to the BN. To see this, first index the variables defining the problem so that

$$T_1(\mathbf{X}) = \{X_1, X_2, \dots, X_{i(1)}\} \quad (7)$$

$$\vdots$$

$$T_2(\mathbf{X}) = \{X_{i(1)+1}, X_{i(1)+2}, \dots, X_{i(2)}\} \quad (8)$$

$$T_j(\mathbf{X}) = \{X_{i(j-1)+1}, X_{i(j-1)+2}, \dots, X_{i(j)}\} \quad (9)$$

$$\vdots$$

$$T_{k+1}(\mathbf{X}) = \{X_{i(k)+1}, X_{i(k)+2}, \dots, X_n\} \quad (10)$$

Notice that by construction, the random variables and the decision variables are now listed in an order consistent with how the DM believes the historical

ordering in which events happen and decisions are taken, i.e.,

$$\begin{aligned} &X_1, X_2, \dots, X_{i(1)}, d_1, X_{i(1)+1}, X_{i(1)+1}, \dots, \\ &X_{i(2)}, d_2, \dots, X_{i(k-1)+1}, X_{i(k-1)+2}, \dots, X_{i(k)}, d_k, \\ &X_{i(k)+1}, X_{i(k)+2}, \dots, X_n \end{aligned} \quad (11)$$

For each $d(\mathbf{X}) \in A$, it is now possible to write down a factorization of densities, valid for all $d(\mathbf{X}) \in A$ and consistent with the ordering above that in turn can form the basis of a graphical representation of a decision problem. Thus, let $p(\mathbf{x}, u|d(\mathbf{X}))$ denote the joint mass function or density over the variables $\mathbf{X} = (X_1, X_2, \dots, X_n)$ and u the utility function, given that the DM takes the decision rule $d(\mathbf{X})$. By the familiar conditioning rules,

$$p(\mathbf{x}, u|d(\mathbf{X})) = p(u|\mathbf{x}, d(\mathbf{X})) \cdot p(\mathbf{x}|d(\mathbf{X})) \quad (12)$$

where

$$\begin{aligned} p(\mathbf{x}|d(\mathbf{X})) &= p_1(T_1(\mathbf{x}))p_2(T_2(\mathbf{x})|T_1(\mathbf{x}), d_1(d(\mathbf{X}))) \dots \\ &\quad p_j(T_j(\mathbf{x})|T^{(j-1)}(\mathbf{x}), d^{(j-1)}(d(\mathbf{X}))) \dots \\ &\quad p_k(T_k(\mathbf{x})|T^{(k-1)}(\mathbf{x}), d^{(k-1)}(d(\mathbf{X}))) \\ &\quad p_{k+1}(T_{k+1}(\mathbf{x})|T^{(k)}(\mathbf{x}), d(\mathbf{X})) \end{aligned} \quad (13)$$

Here, for $j = 1, 2, \dots, k+1$ the term $p_j(T_j(\mathbf{x})|T^{(j-1)}(\mathbf{x}), d^{(j-1)}(d(\mathbf{X})))$ is simply the joint density or mass function of the subset of variables $T_j(\mathbf{x})$ conditional on events that have already happened and all decisions $d^{(j-1)}(\mathbf{x})$ committed to under $d(\mathbf{X})$ before these variables. These component densities can be factorized further. Thus

$$\begin{aligned} &p_j(T_j(\mathbf{x})|T^{(j-1)}(\mathbf{x}), d^{(j-1)}(d(\mathbf{X}))) \\ &= \prod_{s=i(j-1)+1}^{i(j)} p_{j,s}(x_s|T^{(j-1)}(\mathbf{x}), x_{i(j-1)+1}, \dots, x_{s-1}, \\ &\quad d^{(j-1)}(d(\mathbf{X}))) \end{aligned} \quad (14)$$

Let the *parents* Q_s of X_s be defined as the set of arguments $\{T^{(j-1)}(\mathbf{x}), x_{i(j-1)+1}, \dots, x_{s-1}, d^{(j-1)}(d(\mathbf{X}))\}$ that appear *explicitly* in the conditional mass function/density $p_{j,s}(x_s|T^{(j-1)}(\mathbf{x}), x_{i(j-1)+1}, \dots, x_{s-1}, d^{(j-1)}(d(\mathbf{X})))$, for at least one $d(\mathbf{X}) \in A$. The parents of X_s are then simply those variables and

subdecisions that, at least for some possible decision rules happening earlier in the listing, might affect the distribution of X_s . Note this set of parents can be discovered directly from the DM, without reference to anything quantitative.

Finally, let the *parents* of the DM's utility function u be the subset of those components of $\mathbf{X} \cup \{d_1(\mathbf{X}), d_2(\mathbf{X}), \dots, d_k(\mathbf{X})\}$ that appear *explicitly* as arguments of u . Again note that the parents of u can be directly elicited as those features of the problem that might influence how well the DM assesses she has performed after everything has happened.

Note that for complicated problems in which the order decisions need to be made is clear, to simplify the ID, it is suggested in [1] that we omit the edges from one decision node to another – this is sometimes called the *no forgetting* construction.

Once the analyst has elicited the parents of decision variables, random variables, and utilities in the DM's formulation of her problem, a graph can be drawn that depicts the interrelationships between all the variables in the problem and provides a framework within which the DM's Bayes decision rule can be calculated.

Drawing and Analyzing an Historic Influence Diagram

An ID has three sorts of nodes as its vertices: chance nodes (represented by $\circ$), decision nodes (represented by $\square$), and utility nodes (represented by $\diamond$). In the notation above, the chance nodes are the ordered components $X_i, 1 \leq i \leq n$, the decision nodes are the subdecisions $(d_1, d_2, \dots, d_k)$, and the utility node is U . To draw the ID I – here called the *historic* ID – simply draw a connected edge from each parent of a vertex to that vertex, where a node's parents are defined above. By doing this, we simply connect each vertex, whether a chance, decision, or utility node to other factors that might have “influenced” it. Thus, if the vertex is a random variable, it is attached by an edge from random variables and subdecisions that might influence its distribution. If the vertex is a decision node, then a directed edge attaches to it from all variables and decisions that are known to the DM – and therefore, possibly taken account of – at the time she has to commit to her subdecision. Finally, all the variables and decisions influencing the evaluation of the efficacy of a chosen decision rule connect into the utility node.

The example in the section titled “The Semantics of Influence Diagrams” has a historic ID I shown in Figure 5.

Being first, the concentration B has no parents and the decision I also has no parent because B is unknown when the size of the experiment is decided upon. The test results X depend both upon the length of the experiment and the toxicity of the constituent, and so has parents (I, B) . The decision c about the concentration to use in the product can be made having observed X and taking into account the resolution I of the experiment, so it has parents (I, X) . Finally, the utility has parents I because the longer the experimental period the greater the loss, and also c and B , since both profits and reputation depend upon marketing a product with as high as possible safe concentration.

There are various observations we can make from this simple graph:

1. Note that this expresses pictorially and very directly the explanation given above and the semantics are easy to explain to the DM. Notice also that unlike the decision tree, there is no problem that the variables in the problem may be continuous.
2. Like the BN, this graph provides an elegant framework around which to store elicited probabilistic information. Thus, the two probability tables here are the margin of B : the DM’s prior probability of the highest safe concentration and the probability distribution of the test results X , given the value of B and the length of the experiments (i.e., given all the different configurations of the pairs of value of its parents).

Figure 5 A historic influence diagram for Example 2

3. IDs can often be drawn to different levels of resolution. For example, in the illustration above, we could include explicitly as two chance nodes the profit and the reputation of the company or more information could be represented about both the underlying toxicity, and the test result X . In practice, both of these would often be vectors whose components could be vertices of I and whose lack of mutual dependence structure could be coded through missing edges in the graph. Typically, as for the ID described above, such encoded dependence structures can then be used to interrogate the model, elegantly store further elicited information, and also be used in fast computational algorithms for identifying Bayes decision rules. However, there is obviously a trade-off here between the detail presented and the transparency of the graph. Care also needs to be taken that the elaborated decision problem remains uniform.
4. The description of a decision problem can sometimes be dramatically simplified once the dependence structure becomes clear. The easiest such simplification to perform is when, on drawing an ID, you notice that a decision or chance node – called a *barren node* in the diagram – is the parent of no other node. It can be then proved (see [1]) that, for purposes of identifying a Bayes decision rule, we can equally work with the ID that omits this barren node and its connected edges.
5. As more vertices and edges are added, the diagram starts to become opaque. Various authors suggest different methods for simplifying the ID. For example, Shachter [1] suggests omitting edges between decision nodes (the no *forgetting convention*), while Dawid [16] foregoes the inclusion of any parents of decision nodes. However, these modifications make the graph less expressive. The ID can also be made more expressive. Thus analogs of the d -separation theorem for BNs can be used to determine whether a subdecision associated with a Bayes decision rule *needs* to depend on a particular variable (decision or chance) whose values have been observed or whether it can be ignored. In the latter case, edges can be dropped from the irrelevant variable into that decision (see e.g. [2, 17]); then new barren nodes can appear that can be deleted from the ID.

Extensive Form Influence Diagrams and Calculating a Bayes Rule

An ID can also be used as a framework for rollback and thus for discovering a Bayes decision rule. However, the historic influence diagram is not appropriate for this calculation, in general, because it is constructed consistently with the order variables are believed to happen rather than the order in which they are observed. So – like the causal decision tree – the historic ID is a great tool for problem representation and for storing elicited prior information (see **Decision Trees**). However, to be useful as a framework for backward induction, it needs to be transformed so that it is more like the dynamic programming tree (see above).

To draw an *extensive form ID* from an historic ID, we need to reorder the components of $\mathbf{X}$ so that they are consistent with the order in which they *become known* to the DM. In particular, this reordering must ensure that

1. as with historic IDs, any variable X_i known when d_i is taken appears before d_i in the analogous conditioning order (equation 11), $1 \leq i \leq k$;
2. any component variable X_s whose value is *unknown* when d_i is taken, appears *after* d_i in the analogous conditioning order (equation 11) (even if it has actually happened before this decision).

Typically, to transform an historic ID to an extensive form ID, we simply need to permute the order of appearance of some of the component chance variables, using the law of total probability and Bayes rule. Note that reversing conditioning sometimes induces further dependencies between variables in the problem.

By doing this, we obtain a new graphical representation with the same vertices, some edges sometimes reversed, and with some additional edges into chance nodes, sometimes added. The extensive form ID of the running example is given in Figure 6.

Notice that, in this case, the extensive form ID is identical to the historic ID except the directed edge from B to X has been replaced by one from X to B , i.e., this arc has been reversed. The distribution of X given each decision I and the distribution of B given X , both need to be calculated using the law of total probability and Bayes rule, making use of the densities encoded in the historic ID.

Figure 6 An extensive form influence diagram

A Bayes decision rule can now be calculated using an analogous algorithm to the rollback algorithm described above for decision trees (see **Decision Trees**). This algorithm again uses the existence of a Bayes decision rule that assumes that from all situations arrived at in a decision sequence, future decisions can be supposed to be expected utility maximizing. We note the following:

- Being rather technical, a precise description of the rollback algorithm for extensive form IDs is beyond the scope of this article, but is described in [1]. Chapter 8 in [9] contains a good review of these methods. It has subsequently been discovered that sometimes it is possible to evaluate a Bayes decision rule more efficiently using methods not based on rollback [8]. However, for the practitioner it suffices to know that software algorithms are available to automatically calculate a Bayes decision rule for any given historic ID.
- It is actually possible to generalize the construction above so that it applies to a somewhat larger class of problems than those discussed above (see [2, 9]), although we would then need to be more careful how the objects in the graph are defined to keep the construction formal. It is also often possible to construct extra variables artificially and so construct a uniform decision problem from one that is not – see below. However, this latter type of constructive approach can introduce new technical difficulties and loses some of the interpretable appeal of the graph.
- There are other methods for depicting decision problems in an equally formal way (see [9]).

Causal Bayes Nets

There has recently been much interest in the study of models that are called *causal*. Several authors subsequently realized [16, 18] that such models could be seen as a particular example of the historic ID described above. Consider the following hypothetical scenario.

Example 3 Males diagnosed with low sperm count can take an available fertility treatment F . The treatment – a one-off course of pills – is known to sometimes increase the sperm count S of some men. However, taking the treatment has a risk: in a small number of individuals, taking F increases the probability of high blood pressure B in later life, leading to a higher risk of a heart attack H . Expert judgment is that across the population of males being administered the drug, the DAG of the BN below (Figure 7) is valid, with an associated factorization formula of the joint mass function $p(f, s, b, h)$ of these variables and obvious notation:

$$p(f, s, b, h) = p_F(f)p_S(s|f)p_B(b|f)p_H(h|b) \quad (15)$$

The BN G_1 contains two statements: once given his blood pressure, risk of future heart attack is not affected by whether the man took the treatment; and given he takes the treatment, his sperm count is uninformative about his future blood pressure and risk of heart attack.

Note, it can be checked, using the semigraphoid axioms, that G_1 contains exactly the same irrelevance statements as, for example, G_2 (see Figure 8).

Now assume that the expert judgment encoded in G_1 is correct. Then it could be argued that by writing G_1 , the expert might be prepared to not only assert the conditional independence in the observed (or *idle*) system as above *but also* the probability distribution of the process, if it is manipulated – i.e., about the causal connections between the variables above. Unlike the BN, such a graph would distinguish between G_1 and G_2 , assigning a meaning to the directionality of edges in the graph. How various

Figure 7 A DAG for Example 3

Figure 8 An equivalent DAG

Consider the situation described in G_1 , but modified to the prediction of what would happen if the fertility treatment was imposed $\{f = 1\}$ on all such men. Call this manipulation $\{do F = 1\}$. Then the effects of this policy might be that in this manipulated system, $\{f = 1\}$ would happen with probability 1 and the density $p(f, s, b, h|do f = 1)$ would be given by

$$p(s, b, h|do f = 1) = p_S(s|f = 1)p_B(b|f = 1)p_H(h|b) \quad (16)$$

While, if we banned the sales of the treatment, $\{f = 0\}$ would happen with probability 1 and

$$p(s, b, h|do f = 0) = p_S(s|f = 0)p_B(b|f = 0)p_H(h|b) \quad (17)$$

Note that in this case, $p(s, b, h|do f = 1) = p(s, b, h|f = 1)$ and $p(s, b, h|do f = 0) = p(s, b, h|f = 0)$. However, if the man receives another treatment in the future, which forces his blood pressure to be high $\{do b = 1\}$, then this cannot affect whether or not he previously took the fertility drug or whether he previously had an increased sperm count. Furthermore, we might expect his probability of a heart attack to be as high as in the idle system. Thus, given G_1 accurately represents the causal chains in the system, we could expect to infer that

$$p(s, f, h|do b = 1) = p_F(f)p_S(s|f)p_H(h|b = 1) \quad (18)$$

Note that this time this is not the same formula as for $p(s, f, h|b = 1)$, which is given by

$$p(s, f, h|b = 1) = \frac{p_F(f)p_B(b = 1|f) \times p_S(s|f)p_H(h|b = 1)}{p_F(f = 0)p_B(b = 1|f = 0) + p_F(f = 1)p_B(b = 1|f = 1)} \quad (19)$$

authors [18–20] suggest this might be done is given below.

This difference should be expected. If we subsequently learn that a man has high blood pressure, we

would infer that it is more likely he took the treatment that tends to cause this effect. On the other hand, if the man's blood pressure was made high by a subsequent treatment this tells us nothing about what it might have been before and so nothing about whether he had taken the original treatment.

In general, [19] and [18] suggest that we can legitimately call a BN G "causal". Suppose that for *each* variable X in G and each of its possible values x the manipulation $\{do\ X = x\}$ has the effect described above. Thus, after all such manipulations, the DM believes that (a) the new mass function conditional on the manipulation $\{do\ X = x\}$ of all variables Y occurring after X in G , will be equal to the corresponding mass function conditional on *observing* $\{X = x\}$ (in the factorization of the unmanipulated system associated with G), (b) the new mass function, conditional on the manipulation of all other variables Y (except X), will be as it was in the unmanipulated system, had $\{X = x\}$ **not** been observed, (c) the new mass function conditional on the manipulation sets X to x with probability 1. If this truly expresses what the DM believes about the system, then G is called a *causal Bayes Net*. Note that causal BNs assert much more than the BN alone. In particular, unlike the Bayes Net, if the DAGs of two causal BNs are different, then they assert different things. For example, the DAGs G_1 and G_2 above are equivalent representations of the same BN, but as causal BNs they assert very different things about the expert's predicted effects of controlling the system.

We can, in fact, represent a causal BN as an ID. Using the no forgetting convention [1], this can be drawn as in Figure 9.

Figure 9 Causal BN as influence diagram

Here, for example, the decision variable D_B chooses between three options: to leave blood pressure to develop naturally, to medicate to lower the pressure, or to force it to be high. The probability tables associated with these different decisions simply follow the convention outlined above. Causal BNs give a far from general framework for expressing *all* types of causal structures. Their semantics are severely restricted and in particular, imply that the class of possible causal manipulations can only convert the BN into a uniform decision problem. Furthermore, in any given context, it may not be at all clear *which* parameterization of variables to use and exactly *what* doing a variable would actually mean. Thus, in the example above, what we mean by forcing blood pressure to be high is ambiguous, unless further elaborated (see [21, 22] for further discussion of this point).

However, in some problems, especially those associated with outputs of networks of simulators where variables are functionally defined and interventions unambiguous, they have provided a very useful and evocative tool to unpick and explain complicated control problems.

Links between Influence Diagrams and Decision Trees

Even when decision trees are used to represent a problem, it is now common to represent the dependence structure between some of its variables using a BN. Thus, for example, the historic BN of the decision problem described in the article on *decision trees* is simply represented as in Figure 10.

However, what is not sometimes realized, is that many problems expressible as decision trees are not uniform and so cannot be directly expressed as IDs. The decision problem used as a running example for the decision tree section above is such a problem. It is sometimes possible to construct dummy variables, so that within this new framework, the decision problem *is* uniform. However, such constructions are often contrived, involve the addition of many extra

Figure 10 Another historic BN

edges, and more variables as functions of others in the ID, and so are less than transparent and can lose the conditional independence structure that was there originally. This might not matter so much for computational algorithms, but for model description and exploration, it does.

Various hybrid forms of trees, BNs, and IDs now exist (for example, see [23–25]), as well as other competing graphical representations of problems (see e.g. [26–28]). These methods are typically very powerful, but are either semantically more complicated or suited to the representation of more specific kinds of decision problems than the ID and decision tree.

Informational Value of Corporate Issuer Credit Ratings

The quality of corporate issuer credit ratings^a provided by Standard & Poor's (S&P) (*see Credit Scoring via Altman Z-Score; Enterprise Risk Management (ERM)*) and Moody's (*see Risk in Credit Granting and Lending Decisions: Credit Scoring; Default Risk*) has come under closer scrutiny. Whether justified or not, the most talked about Enron and WorldCom cases intensified the debate on rating quality. The majority of investors believe that ratings are accurate measures of the issuer's creditworthiness. However, investors are less satisfied about their timeliness. Several surveys, conducted in the United States, reveal that most investors believe that rating agencies are too slow in adjusting their ratings to changes in the creditworthiness.^b At the same time, investors prefer some degree of rating stability to avoid frequent rebalancing of their portfolios, even when the underlying credit risk fundamentals justify rating migrations. Apparently, investors want both stable and timely ratings, which are two conflicting objectives. It is a dilemma for investors. Moody's tries to find a compromise: *"Moody's analysts attempt to balance the market's need for timely updates on issuer risk profiles, with its conflicting expectation for stable ratings"* [1].

Some critics argue that the unsatisfactory timeliness in ratings is mainly the result of a lack of competition in the National Recognized Statistical Rating Organization (NRSRO) rating industry. Because of legal and contractual restrictions, most institutional investors are only allowed to invest in companies rated by an agency with an NRSRO status. In order to have access to the capital market, companies are forced to have ratings from NRSRO agencies. By the end of 2006 only five agencies, namely, S&P, Moody's Investor Services, Fitch, A.M. Best, and the Canada's Dominion, had obtained this status from the SEC. Even though the legal basis of the NRSRO status is only found in the United States, an NRSRO rating is a necessary condition for large international companies to have sufficient access to the international capital market. In practice the two largest agencies S&P and Moody's are close to a duopoly,

since large companies prefer to have at least two ratings and market participants expect large companies to have more than one rating opinion. In practice this works fine as the ratings assignments of major rating agencies largely agree with each other.

To allow more competition in the rating industry, the US Congress approved the Credit Rating Agency Reform Act in September 2006. This act introduces a new system of voluntary registration, so any rating agency that can show a good track record – subject to objective criteria – can obtain an NRSRO designation. To what extent this act will change the rating industry depends on the use of ratings. Do ratings provide credit risk information in the first place or do ratings serve the certification need – to check whether portfolio's meet the portfolio eligibility standards set by regulators, fund trustees, or boards of directors? The first objective requires ratings to be superior by being timely and accurate while the second objective demands for some level of rating stability. A benchmark study with credit scores which proxies for the actual point-in-time credit quality shows that ratings exhibit a high rating stability: the number of rating migrations is lowered by a factor 2.5. However, the stability objective – achieved by the agencies' through-the-cycle methodology is at a high cost: ratings are delayed by 8–9 months and the default prediction performance of ratings is seriously affected: for a 1-year prediction horizon the accuracy ratios drop by 9.9% relative to a long-term point-in-time perspective. A shift to a more balanced equilibrium between rating stability and rating timeliness might result when the rating industry becomes more competitive – as intended by the new act.

The sections titled "Motivations to Increase Rating Stability" and "Rating Stability Enhancement by a Through-the-Cycle Methodology" describe the motivations to increase rating stability and how agencies achieve rating stability by a through-the-cycle methodology. The section titled "Costs of Rating Stability in Terms of Rating Timeliness and Default Prediction Performance" reports the costs of rating stability in terms of rating timeliness and default prediction performance. The section titled "The added value of rating outlooks and rating reviews" completes this quantitative picture by examining the added value of rating outlooks and rating reviews. The section titled "A New Balance Between Rating Timeliness and Stability due to More Competition?" concludes with an outlook for the rating industry.

Motivations to Increase Rating Stability

A number of arguments can be put forward to strive for some level of rating stability.

1. Investors do not want ratings to be changed to reflect small changes in the companies' financial condition, which are likely to be reversed in the near future. This will force investors to rebalance their portfolio's unnecessarily to meet the portfolio eligibility standards. By following this line of reasoning, S&P [2] is convinced that stable ratings are of most value to investors. Companies – paying for the agency rating services – also prefer rating stability, which prevents continuous renegotiation with investors and banks.
2. From a supervisory perspective, rating stability is desirable to prevent procyclicality effects. A prompt and full response to changes in actual creditworthiness could deepen a financial crisis. Linkages of portfolio strategies and portfolio mandates with ratings and, in future, linkages of bank capital requirements with ratings, can force banks and investors to liquidate their positions hurriedly, which might ultimately result in a credit crunch. Rating stability could soften these procyclicality effects.
3. Rating stability supports the reputation of agencies. Rating reversals within a short period have a negative impact on an agency's reputation, even when they reflect true changes in creditworthiness. It is better to be late and right, rather than fast and wrong.
A strong reputation, which underlies the recognition of ratings in financial markets, is in the interest of not only the agencies themselves but also that of authorities, investors, and bond issuing companies. It ensures a broad acceptance of ratings within the financial community, which is essential to lower information costs of investors and fuel the investment flow in corporate bonds.
4. From an organizational perspective, a rating stability objective keeps the costs of internal reviewing and monitoring under control because rating assignments are based on costly and labor-intensive in-depth analyses of companies. An ambitious timeliness objective would require a complete redesign of the rating assignment process. In this case monitoring and reviewing will

have to rely for an important part on automatic processing of statistical data to keep the cost level of rating services at a reasonable level. Nevertheless, because of reputation effects, agencies are likely to use automatic analysis for monitoring purposes.

Rating Stability Enhancement by a Through-the-Cycle Methodology

Agencies aim to balance rating stability and rating timeliness by a through-the-cycle methodology. This methodology has two aspects: first, a focus on the permanent component of default risk, and second, a prudent migration policy.

The first aspect of the through-the-cycle rating methodology refers to its name. By filtering out the temporary component of default risk, only the permanent, long-term, and structural component is measured. The second – less well known – aspect of the through-the-cycle methodology is the enhancement of rating stability by a prudent migration policy. Only substantial changes in the permanent component of default risk lead to rating migrations and, if triggered, ratings are only partially adjusted to the actual level in the permanent component of default risk. Although not officially disclosed by agencies, Moody's provided some insight in January 2002, stating that its migration policy was to be reconsidered: *“Under consideration are more aggressive ratings changes – such as downgrading a rating by several notches immediately in reaction to adverse news rather than slowly reducing the rating over a period of time – as well as shortening the rating review cycle to a period of weeks from the current period of months”*.^c

Precisely how rating agencies put their through-the-cycle methodology into practice is not clear. Treacy and Carey [3] describe the through-the-cycle rating methodology as a rating assessment in a worst-case scenario, at the bottom of a presumed credit quality cycle. Altman and Rijken [4] characterize the migration policy as follows. A rating migration is triggered, when the actual permanent credit risk component exceeds a threshold of 1.25 notch steps, relative to the average “through-the-cycle credit quality” in a particular rating class.^d If triggered, the rating migration only closes 75% of the gap between the current rating level and the target rating level. Although these parameters do not seem to point to an

extreme prudent migration policy, they are sufficient to cause a significant enhancement in rating stability.

In contrast to the through-the-cycle methodology, investors judge the corporate credit quality from a point-in-time perspective, on the basis of the actual position in the corporate credit cycle. Bankers have a point-in-time perspective on corporate credit quality with a time horizon of between 1 and 7 years (*see* Basel Committee [5]; **Potency Estimation**). It is reasonable to assume that this perspective applies to other investors as well. As opposed to through-the-cycle measurement approach, the point-in-time perspective looks at the actual default risk without an attempt to suppress the temporary component in default risk.

Costs of Rating Stability in Terms of Rating Timeliness and Default Prediction Performance

A drawback of the through-the-cycle perspective is its mismatch with the investor's point-in-time perspective. The cost of rating stability enhancement is a deterioration of rating timeliness and default prediction performance. Altman and Rijken [6] have carried out a benchmark study for S&P issuer credit ratings with credit scores to quantify these costs and to separate out the contributions of the two aspects of the through-the-cycle methodology – the long-term perspective and the prudent migration policy – to the rating stability level. Reference point to measure rating stability is the investor's long-term (6-year) point-in-time perspective.

Table 1 lists the quantitative consequences of the agencies' through-the-cycle methodology from a 6-year point-in-time perspective for Moody's issuer credit ratings.^c From a point-in-time perspective on default risk, weighting both permanent and temporary component of default risk, the through-the-cycle methodology lowers the annual rating migration probability by a factor of 2.6 and delays the timing of rating migrations by 8 months on the downgrade side and by 9 months on the upgrade side. As a result, the through-the-cycle rating methodology affects the accuracy of default prediction: from a long-term point-in-time perspective the accuracy ratio drops by 9.9% for 1-year default prediction horizon. As expected, for a 6-year prediction horizon the negative impact of the through-the-cycle methodology is less severe: -3.3%.

The through-the-cycle methodology seriously affects the short-term default prediction performance of ratings. It fully offsets the information advantage agencies naturally have. Rating agencies have resources, capabilities, and access to private information to produce better estimates on credit quality than (outside) investors. In terms of accuracy ratios, their information advantage is about 3% compared to simple credit scores including market information (for example, EDF scores of Moody's KMV; *see* **Credit Scoring via Altman Z-Score**). This information advantage does not seem impressive, but it is extremely difficult to add new information on top of credit score information, including stock price information, which reflects a market opinion consensus.

The Added Value of Rating Outlooks and Rating Reviews

For a complete quantification of the information signaled by agencies, rating outlooks and rating reviews must be taken into account. In addition to their corporate issuer credit ratings, agencies provide rating outlooks and rating reviews. Rating outlooks signal the likely direction of a rating migration in one to two years' time. In response to an event or an abrupt break in a trend, a corporate issuer credit rating is placed on a Watchlist by Moody's, on CreditWatch by S&P, or on a rating Watch by Fitch. In these Rating Review cases, ratings are said to be under review and the outcome is disclosed typically within 90 days.

Although outlooks – rating outlooks and rating reviews – are not meant to be a correction for ratings in the first place, one can use them as a secondary credit risk measure on top of the rating scale. One can add the information of rating outlooks and rating reviews to ratings by adding or subtracting two or three notch steps depending on the type and sign of outlooks. A study by Cantor and Hamilton [7] reveals that the adjustment of ratings significantly improves default prediction performance. The accuracy ratio increases by 4% for a 1-year prediction horizon.

Outlook information is not sufficient to compensate for the negative impact of the through-the-cycle methodology. Potentially, adjusted ratings do have a long-term point-in-time perspective when agencies standardize credit risk information in the outlook scale. As outlooks are not intended to quantify credit risk information explicitly, agencies have not

Table 1 Effects of the through-the-cycle methodology on rating properties from a long-term point-in-time perspective^(a)

	Rating stability Reduction factor in number of rating migrations	Rating timeliness Delay in rating migrations (months)		Default prediction performance Decrease in accuracy ratio (%)	
		For downgrades	For upgrades	1-year prediction horizon	6-year prediction horizon
Effects due to the two aspects of the through-the-cycle methodology from a long-term (6-year) point-in-time perspective					
1. Filtering the temporary credit risk component	×0.75	4.4	3.8	6.9	2.1
2. Prudent migration policy	×0.5	3.4	5.1	3.0	1.2
Total through-the-cycle (TTC) effect	×0.4	7.8	8.9	9.9	3.3

^(a)Results are obtained for Moody's ratings in the period 1982–2005

standardized credit risk information in the outlook assignment process. Credit risk standardization in the outlook scale could improve the default prediction performance of adjusted ratings even further with another 4–6% and could enable to bridge the gap between the agencies' through-the-cycle perspective and the investor's point-in-time perspective. In that case agencies can make full use of their information advantage and also become competitive on rating timeliness and default prediction performance with other credit risk information providers.

A New Balance Between Rating Timeliness and Stability due to More Competition?

In relative transparent markets of US listed companies, corporate issuer ratings have little informational value for investors even when Rating Outlook and Rating Review information is added. The rating stability objective fully offsets the agencies' information advantage. Apparently, agencies have strong incentives to give the rating stability objective priority over a superior timeliness or informational objective. So agencies fulfill most of all the certification needs of investors while investors obtain their up-to-date credit risk information from a wide range of other providers focusing on point-in-time credit risk information.

As the business of credit risk information providers is growing since 2001 and become more sophisticated, agencies can't compromise rating quality too much with their prudent rating through-the-cycle methodology. Credibility is a crucial

condition. Since 2001 the reputation of the major agencies is at stake. Agencies might have pushed the rating stability objective too far. A prudent approach to protect their reputation works well in a relative stable financial environment. However, in volatile capital markets and a more competitive rating industry, agencies must provide more timely information to protect their credibility as rating institutions. So, after the Enron and WorldCom debacles, in 2002 Moody's intended to change ratings more aggressively and update them more frequently, in response to a demand for more rating timeliness. Moody's renounced this intention, after broad consultation with investors, companies, and financial authorities. In their meetings Moody's repeatedly heard that investors value the current level of rating stability and do not want ratings simply to follow market prices. Moody's therefore decided not to change their rating policy, and they continue to produce stable ratings (see Fons *et al.* [8]).

More competition after approval of the Credit Rating Agency Reform Act can put more pressure on the agencies to search for an optimal balance between rating stability and rating timeliness. Although companies are the formal clients of rating agencies, the investor opinion is more important in setting the balance between rating stability and rating timeliness, which will show up in a more competitive rating industry. The NRSRO designation requirement set by regulators, fund trustees, or boards of directors in the portfolio eligibility standards are probably going to be replaced by a list of agencies based on reputation and worldwide coverage. In that case the dominant

market share of Moody's, S&P, and Fitch will not be challenged in the short term. However, in contrast to the past situation, their position in the long run will not be protected by an NRSRO designation alone but also by a track record in rating quality performance. Consequently agencies will have to push their balance between rating stability and rating timeliness more to the edge and serve both the certification needs and information needs of investors.

Presumably only a restricted number of major rating agencies will survive in free market circumstances. Portfolio eligibility standards have to be widely accepted, so investors prefer a restricted number of rating agencies, which limits conflicting rating opinions and safeguards the consistency in the rating scale. Most investors understand the current standards AAA (Aaa)–CCC (Caa) of the major rating agencies. A large number of rating agencies would probably result in rating scale diversity. This could result in a decline of the rating standards and damage the certification function of ratings. A new task of the SEC should be to preserve some general accepted standards in the measurement of credit risk.

The implementation of Basel II, the strong increase in structured products, the strong growth of financial markets in emerging economies, and the disintermediation in financial markets have greatly stimulated the demand for ratings in less transparent markets. This huge increase in demand can probably not be absorbed by a few major agencies, so a large number of smaller agencies will emerge focusing on niche markets. For the success of these new agencies, the key will be whether they can develop sufficient credibility to serve the certification needs of investors. This can be done by building a good track record in rating stability as well as rating timeliness and default prediction performance.

End Notes

^a. In the remainder of this article, ratings refer to the corporate issuer credit ratings of S&P, Moody's, and Fitch, unless stated otherwise.

^b. See, for example, the surveys of the Association for Financial Professionals (AFP) in 2002 and 2004. A similar case has been made earlier by Ellis [9] and Baker and Mansi [10]. The AFP survey reveals that 83% of the investors believe that, most of the time, ratings accurately reflect the issuer's

creditworthiness. On the other hand, all surveys show that investors are not satisfied with the timeliness of ratings. This complaint does not only arise from the particular Enron and WorldCom cases. Halfway the nineties the survey by Ellis showed that 70% of investors believed that ratings should reflect recent changes in default risk, even if they are likely to be reversed within a year.

^c. See *The Financial Times*, 19 January 2002, "Moody's mulls changes to its ratings process".

^d. This threshold level is derived for a monitoring frequency of one year.

^e. Results of the benchmark study for Moody's ratings published in this paper largely agree with the results for S&P ratings published in Altman and Rijken [6].

HERBERT A. RIJKEN AND EDWARD I. ALTMAN

Insurability Conditions

What does it mean to say that a particular risk is insurable? This question must be addressed from the vantage point of the potential supplier of insurance who offers coverage against a specific risk at a stated premium. The policyholder is protected against a prespecified set of losses defined in the contract^a.

Two conditions must be met before insurance providers are willing to offer coverage against an uncertain event. Condition 1 is the ability to identify and quantify, or estimate, the chances of the event occurring, and the extent of losses likely to be incurred when providing different levels of coverage. Condition 2 is the ability to set premiums for each potential customer or class of customers. This requires some knowledge of the customer's risk in relation to others in the population of potential policyholders. If Conditions 1 and 2 are both satisfied, a risk is considered to be insurable. But it still may not be profitable. In other words, it may be impossible to specify a rate for which there is sufficient demand and incoming revenue to cover the development, marketing, and claims costs of the insurance and yield a net positive profit. In such cases, the insurer will opt *not* to offer coverage against this risk.

Condition 1: Identifying the Risk

To satisfy this condition, estimates must be made of the frequency at which specific events occur and the magnitude of the resulting loss. Such estimates can use historical data from previous events, such as peril of fire, or scientific analyses of what is likely to occur in the future, such as earthquake peril. New developments in catastrophe risk modeling have made it easier to estimate the risk facing insurers when they are considering how much coverage to provide in hazard-prone areas.

Collecting Data on Risks

Rating agencies typically collect data on all the losses incurred over a period of time for particular risks and exposure units. Suppose the hazard is fire and the exposure unit is a well-defined entity, such as a \$300 000 wood-frame home in California, to be insured for 1 year. The typical measurement is the

pure premium (PP), which is the basis for setting an actual premium for potential customers. The PP is defined as

$$PP = \frac{\text{total losses}}{\text{total number of exposure units}} \quad (1)$$

The PP normally considers loss adjustment expenses for settling a claim. We assume that this is part of total losses. For more details on calculating PP, see Launie *et al.* [2].

Assume that the rating agency has collected data on 100 000 wood-frame homes in that state and has determined that the total annual loss from fires to these structures over the past year is \$20 million. If these data are representative of the expected loss to this class of wood-frame homes in California next year, then, using equation (1), the PP is given by

$$PP = \frac{\$20\,000\,000}{100\,000} = \$200$$

This figure is simply an average. It does not differentiate between wood-frame homes of different values, their locations in the state, the distance of each home from a fire hydrant, or the quality of the fire department serving different communities. All of these factors are often taken into consideration by underwriters who specify a premium that reflects their estimate of the risk to particular structures.

Insurance providers use scientific studies by seismologists, geologists, and structural engineers to estimate the frequency of earthquakes of different magnitudes, as well as the damage that is likely to occur to different structures from such earthquakes.

Condition 2: Setting Premiums for Specific Risks

Once the risk has been identified, the insurer needs to determine what premium it can charge to make a profit while not subjecting itself to an unacceptably high chance of a catastrophic loss. There are a number of factors that play a role in determining what prices companies would like to charge. Owing to problems of ambiguity aversion (for uncertain probabilities), adverse selection, moral hazard, and highly correlated losses, insurers may want to charge premiums that considerably exceed the expected loss.

Insurability Conditions and Demand for Coverage

For some risks the desired premium may be so high that there would be very little demand for coverage at that rate. In such cases, even though an insurer determines that a particular risk meets the two insurability conditions discussed above, it does not invest the time and money to develop the product.

More specifically, the insurer must be convinced that there is sufficient demand to cover the development and marketing costs of the coverage through future premiums received. If state regulations restrict the price insurers can charge for certain types of coverage, then companies may not provide protection against these risks. In addition, if an insurer's portfolio leaves it vulnerable to the possibility of extremely large losses from a given disaster because of adverse selection, moral hazard, and/or high correlation of

risks, then again the insurer may be unwilling to provide coverage against such disasters.

Insurance Applications of Life Tables

Causes of risk in life insurance (*see Risk Classification/Life*) relate to financial aspects (e.g., investment yield, inflation, etc.), demographical aspects (e.g., lifetimes of policyholders, frequency of disability, lapses and surrenders, etc.), and expenses. In this article, we deal with demographical aspects only, focusing on insureds' lifetimes, which in turn determine the mortality, namely the frequency of death in a life insurance portfolio (or a pension plan).

Mortality constitutes an important cause of risk in a life insurance portfolio. A number of risk factors affect individual mortality. At an individual level, the insured's age has a prominent role. Other risk factors are gender, health status, profession, smoking habits, etc. So, formulae used to calculate premiums and reserves for life insurance and annuity products should allow for various risk factors. In particular, the insured's age enters formulae *via* the age pattern of mortality that is a structure linking survival and death probabilities to the attained age (*see Logistic Regression*).

In this article, we first describe the features of a (period) life table that constitutes the basic tool to represent the age pattern of mortality, and the applications of life tables to the calculation of expected present values (or "actuarial" values) in life insurance. Age-discrete and age-continuous approaches to the representation of the mortality pattern are described. We then introduce the ideas underlying the projected life tables, meant as a tool to represent future mortality. Finally, we focus on randomness in the results of a life insurance portfolio (cash flows, profits, etc.), and the use of stochastic models.

Age as a Risk Factor in Life Insurance

Let x denote the insured's age at policy issue. Consider for example, a 1-year insurance cover providing the beneficiaries with the unitary amount at the end of the year if the insured dies within the year. The expected present value or "actuarial" value, ${}_1A_x$, of the benefit is given by

$${}_1A_x = {}_1q_x v \quad (1)$$

where ${}_1q_x$ (or simply q_x) denotes the probability of a person age x dying within 1 year, and v denotes the discount factor, $v = \frac{1}{1+i}$, where i is the annual rate of interest.

Consider an insurance product (the "pure endowment") providing the policyholder with the unitary amount if she/he is alive at time n (the maturity). The actuarial value of the benefit is as follows:

$${}_nE_x = {}_np_x v^n \quad (2)$$

where ${}_np_x$ denotes the probability of the insured being alive at maturity.

An immediate life annuity provides a sequence of annual amounts (e.g., paid at the end of each year) while the beneficiary is alive. Referring to a unitary annual amount, the actuarial value is given by

$$a_x = {}_1p_x v + {}_2p_x v^2 + \dots \quad (3)$$

Actuarial values, like ${}_1A_x$, ${}_nE_x$, and a_x , depend on age x *via* probabilities of death and survival, like ${}_1q_x$ and ${}_hp_x$, expressing mortality as a function of the current age x (as well as the age at the time of payment).

Other risk factors are usually allowed for in actuarial calculations. As regards the insured's gender, it should be noted that males and females have distinct mortality patterns. Specific patterns owing to the health status or profession are commonly expressed as functions of the "normal" mortality. Recognizing the role of various risk factors in determining the individual mortality pattern means that some heterogeneity is allowed for in an insured population.

Life Tables

The life table is a (finite) decreasing sequence $l_0, l_1, \dots, l_\omega$. The generic item l_x refers to the integer age x , and represents the estimated number of people alive at that age in a properly defined population. The exact meaning of the l_x 's is explained after we discuss two approaches to the calculation of these numbers.

Assume that the sequence $l_0, l_1, \dots, l_\omega$ is provided by statistical evidence, that is, by a "longitudinal" observation of the actual numbers of individuals alive at age 1, 2, $\dots$, ω , out of a given initial "cohort" consisting of l_0 individuals. The age ω is the maximum age (say, $\omega = 110$), i.e., the age such

that $l_\omega > 0$ and $l_{\omega+1} = 0$. The sequence $l_0, l_1, \dots, l_\omega$ is called a *cohort life table*. Clearly, the construction of a cohort table takes $\omega + 1$ years.

Assume, conversely, that the statistical evidence consists of the frequency of death at the various ages, observed throughout a given period, for example, 1 year. Assume the frequency of death at age x (possibly after a graduation with respect to x) as an estimate of the probability q_x .

For $x = 0, 1, \dots, \omega - 1$, define

$$l_{x+1} = l_x(1 - q_x) \quad (4)$$

with l_0 (the radix) assigned (e.g., $l_0 = 100\,000$). Hence, l_x is the expected number of survivors out of a notional cohort initially consisting of l_0 individuals. The sequence $l_0, l_1, \dots, l_\omega$, defined by recursion (4), is called a *period life table*, as it is derived from period observations.

Probabilities of death and survival can be derived from a life table. Referring to a person alive at age x , the probability of being alive at age $x + 1$, ${}_1p_x$ or simply p_x , is clearly given by

$$p_x = 1 - q_x = \frac{l_{x+1}}{l_x} \quad (5)$$

More generally, the probability of being alive at age $x + h$ (with h a positive integer number) is given by

$${}_hp_x = p_x p_{x+1} \dots p_{x+h-1} = \frac{l_{x+h}}{l_x} \quad (6)$$

(with ${}_0p_x = 1$).

The probability of dying before age $x + h$ is given by

$${}_hq_x = 1 - {}_hp_x = \frac{l_x - l_{x+h}}{l_x} \quad (7)$$

(whence ${}_0q_x = 0$). Finally, the probability of dying between ages $x + h$ and $x + h + k$ is as follows:

$${}_{h|k}q_x = {}_hp_x {}_kq_{x+h} = \frac{l_{x+h} - l_{x+h+k}}{l_x} \quad (8)$$

Note that, in all symbols, the right-hand side subscript denotes the age referred to. For example, in equation (8) the probability ${}_kq_{x+h}$ relates to an individual age $x + h$, i.e., assumed alive at that age. Conversely, the left-hand side subscript denotes some duration, whose meaning depends on the specific probability addressed (see equations (6–8)).

Probabilities as defined by equations (5–8), underpin the calculation of actuarial values, which can be used to determine premiums (see **Risk Classification in Nonlife Insurance**) and mathematical reserves (provided that the so-called equivalence principle has been adopted). For example, the single premium, Π , for a n -year term insurance providing a death benefit C at the end of the year of death is given by

$$\Pi = C_n A_x = C \sum_{h=1}^n {}_{h-1|1}q_x v^h \quad (9)$$

The single premium for an immediate life annuity paying the annual amount R is given by

$$\Pi = R a_x = R \sum_{h=1}^{\omega-x} {}_hp_x v^h \quad (10)$$

The mathematical reserve of an insurance contract quantifies the insurer's liability related to the policy itself at a given time t . For example, the mathematical reserve, V_t , of a single-premium term assurance is given by

$$V_t = C_{n-t} A_{x+t} \quad (11)$$

while for an annuity (see **Longevity Risk and Life Annuities**) we have

$$V_t = R a_{x+t} \quad (12)$$

However, in a modern, risk-oriented framework both premium and reserve calculations rely on more complex formulae, possibly allowing for the cost of options and guarantees embedded in the insurance product.

For more information about life tables and their use in actuarial calculations, the reader should refer to actuarial textbooks, for example [1, 2]; see also [3]. The construction of life tables is the specific topic of various textbooks, for example [4–6].

“Population” Tables versus “Market” Tables

Mortality data, and hence life tables, can originate from observations concerning a whole national population, a specific part of a population (e.g., retired workers, disabled people, etc.), an insurer's portfolio, etc.

Life tables constructed on the basis of observations involving a whole national population (split into females and males) are commonly referred to as *population tables*.

Market tables are constructed using mortality data coming from a collection of insurance portfolios and/or pension plans. Usually, distinct tables refer to assurances (i.e., insurance products with a positive sum at risk, for example, term assurances and endowments), annuities individually purchased, and pensions (i.e., annuities paid to the members of a pension plan).

The rationale of distinct market tables lies in the fact that mortality levels may significantly differ on moving from one type of insurance product to another. For example, the beneficiary of a purchased annuity usually is a person with a high life expectancy, whence an “adverse selection” affects the mortality pattern in annuity portfolios. Conversely, pensions are paid to people as a straight consequence of their membership of an occupational pension scheme.

Market tables provide experience-based data for premium and reserve calculations and for the assessment of expected profits. Population tables can provide a starting point when market tables are not available. Moreover, population tables usually reveal mortality levels higher than those expressed by market tables and hence are likely to constitute a prudential (or “conservative”, or “safe-side”) assessment of mortality in assurance portfolios. Thus, population tables can be used when pricing assurances, in order to include a profit margin (or a “safety loading”) into the premiums.

Examples of population tables and market tables can be found in [1] and [5].

Moving to a Time-Continuous Context

In a more formal setting, the probabilities previously defined can be expressed in terms of the remaining random lifetime, T_x , of an individual age x . So, we have

$${}_h p_x = \Pr[T_x > h] \quad (13)$$

$${}_h q_x = \Pr[T_x \leq h] \quad (14)$$

$${}_{h|k} q_x = \Pr[h < T_x \leq k] \quad (15)$$

However, equations (6–8) concern probabilities only involving integer ages x and integer times h

and k . Therefore, if we want to evaluate probabilities as in equations (13–15) when ages and times are real numbers, further tools are needed.

Assume that the function $S(t)$, called the *survival function* (see **Hazard and Hazard Ratio**) and defined for $t \geq 0$ as follows:

$$S(t) = \Pr[T_0 > t] \quad (16)$$

has been assigned. Clearly, T_0 denotes the random lifetime for a newborn.

Consider the probability defined by equation (13). Since

$$\begin{aligned} \Pr[T_x > h] &= \Pr[T_0 > x + h | T_0 > x] \\ &= \frac{\Pr[T_0 > x + h]}{\Pr[T_0 > x]} \end{aligned} \quad (17)$$

we find that

$${}_h p_x = \frac{S(x + h)}{S(x)} \quad (18)$$

For the probability defined by equation (14) we obtain

$${}_h q_x = \frac{S(x) - S(x + h)}{S(x)} \quad (19)$$

The same reasoning leads to

$${}_{h|k} q_x = \frac{S(x + h) - S(x + h + k)}{S(x)} \quad (20)$$

Turning back to the life table, note that since l_x is the expected number of people alive out of a cohort initially consisting of l_0 individuals, we have

$$l_x = l_0 \Pr[T_0 > x] \quad (21)$$

and, in terms of the survival function,

$$l_x = l_0 S(x) \quad (22)$$

(provided that all individuals in the cohort have the same mortality pattern, described by $S(x)$). Thus, the l_x 's are proportional to the values the survival function takes on integer ages x , whence the life table can be interpreted as a tabulation of the survival function.

How does one obtain the survival function for all real ages x ? Relation (22) suggests a practicable approach. First, set $S(x) = l_x/l_0$ for all integers

x using the available life table. Next, for $x = 0, 1, \dots, \omega - 1$ and $0 < f < 1$, define

$$S(x + f) = (1 - f)S(x) + fS(x + 1) \quad (23)$$

and assume $S(x) = 0$ for $x > \omega$, whence the survival function is a piece-wise linear function. Interpolation models other than the linear model used in equation (23) can be adopted. Moreover, the values of $S(x)$ can be fitted using some mathematical formula; however, the use of formulae for representing the mortality pattern can be better placed in the framework described below.

Consider the force of mortality (or instantaneous mortality intensity), μ_x , defined for all $x \geq 0$ as follows:

$$\mu_x = \lim_{t \rightarrow 0} \frac{tq_x}{t} \quad (24)$$

The function μ_x can be estimated, for example, for $x = 0, 1, \dots$, using period mortality observations. The estimated values can then be graduated, in particular, using a mathematical “law”. A number of laws have been proposed in actuarial and demographical literature, and are used in actuarial practice. A famous example is given by the Gompertz–Makeham law:

$$\mu_x = A + b c^x; \quad A \geq 0; b, c > 0 \quad (25)$$

An interesting relation links the survival function to the force of mortality. From definition (24), using equation (19), we obtain

$$\mu_x = -\frac{dS(x)/dx}{S(x)} \quad (26)$$

When μ_x has been assigned, relation (26) is a differential equation. Solving with respect to $S(x)$ (with the obvious condition $S(0) = 1$) leads to

$$S(x) = e^{-\int_0^x \mu_t dt} \quad (27)$$

Thus, the survival function can be obtained, and then all survival and death probabilities can be derived (see equations (18–20), with x, h , and k positive real numbers).

Time-continuous models and mortality laws are described in many actuarial textbooks; see, for example [1, 2]. See also [7] and the references therein.

Static versus Dynamic Mortality

An important hypothesis underlying recursion (4), which defines the l_x 's, should be clearly stated. As the q_x 's are assumed to be estimated from mortality experience in a given period (say, 1 year), the calculation of the l_x 's relies on the assumption that the mortality pattern does not change in the future. The same hypothesis underlies the calculation of $S(x)$ (see equation (27)), as μ_x is assumed to be estimated from period mortality data.

In many countries, however, statistical evidence show that human mortality declined over the twentieth century, and in particular, over its last decades. So, the hypothesis of “static” mortality cannot be assumed in principle, at least when long periods of time are referred to. Hence, in life insurance applications, the use of period life tables should be restricted to products involving short or medium durations (5–10 years, say), like term assurances and endowments, while it should be avoided when dealing with life annuities.

Allowing for trends in mortality implies the use of “projected” life tables, representing future mortality on the basis of the experienced mortality trend.

In a “dynamic” context, let $q_x(t)$ denote the probability of an individual age x in calendar year t dying within 1 year. If t denotes a future year, this probability must be estimated on the basis of past observations and hypotheses about future trends. For example, a projection formula frequently used in actuarial practice is as follows:

$$q_x(t) = q_x(\bar{t}) r_x^{t-\bar{t}} \quad (28)$$

where $q_x(\bar{t})$ refers to calendar year $\bar{t}$, for which a recent period life table is available, while r_x ($0 < r_x < 1$) denotes the annual reduction factor of mortality at age x and is estimated on the basis of past mortality experience. The hypothesis underlying equation (28), which is an extrapolation formula, is that the observed mortality trend will continue in future years.

A number of projection methods are at present available. For more information about forecasting mortality and projected life tables, the reader can refer, for example, to [8, 9], and references therein. A survey on mortality modeling in a dynamic context is provided by Pitacco [10].

From the $q_x(t)$'s, survival probabilities can be derived. For instance, for an individual age x in

calendar year t , the probability of being alive at age $x + h$ (i.e., in calendar year $t + h$) is given by

$${}_h p_x(t) = (1 - q_x(t))(1 - q_{x+1}(t+1)) \dots (1 - q_{x+h-1}(t+h-1)) \quad (29)$$

The actuarial value of a life annuity for a person age x in calendar year t is then given by

$$a_x(t) = {}_1 p_x(t)v + {}_2 p_x(t)v^2 + \dots \quad (30)$$

rather than by expression (3).

Deterministic versus Stochastic Mortality

When the probabilistic description of the mortality pattern is only used to derive expected values, a deterministic model is actually adopted. However, mortality within an insurance portfolio (e.g., number of policyholders dying in a given year, number of policyholders alive at maturity, etc.) is random, and this leads to riskiness in portfolio results (cash flows, profits, etc.). In a deterministic context, riskiness can be (roughly) faced *via* the use of prudential mortality assumptions, i.e., including a safety loading in premiums and reserves. However, the magnitude of the safety loading frequently does not rely on a sound risk assessment.

An appropriate alternative is provided by stochastic models. A stochastic approach to mortality recognizes various risk components. Consider, in particular, the following issues.

1. Randomness in mortality is first originated by random fluctuations of the frequency of death around its expected value. The risk of random fluctuations, or “process risk”, is a well-known component of risk in insurance. Its severity (conveniently assessed) decreases as the portfolio size increases, and this fact partially justifies deterministic models.
2. Mortality experienced throughout time may systematically differ from expected mortality. The risk of systematic deviations can be thought of as an “uncertainty risk”, meaning uncertainty in mortality assessment. In particular, future mortality may differ from projected mortality, originating the so-called longevity risk.
3. Finally, the “catastrophic” component of mortality risk consists in the possibility of a sudden and

short-term rise in mortality for example, because of an epidemic or a natural disaster.

Although the life table is the basic tool even for stochastic mortality, a stochastic model requires further inputs. In particular the following items are needed:

1. correlation assumptions among individual life-times (though in actuarial practice the independence hypothesis is commonly accepted);
2. a model representing systematic deviations (for example, consisting of a set of alternative scenarios for future mortality and a probability distribution over the set itself).

A stochastic model provides outputs such as the probability distributions of the number of deaths and related portfolio results (cash flows, profits, etc.), and in particular, single-figure indexes (expectations, variances, percentiles, etc.). Many applications of stochastic mortality models can be envisaged in the field of insurance risk management. For example:

1. pricing of insurance products (in particular, assessment of the safety loading);
2. choice of reinsurance arrangements;
3. capital allocation for solvency (possibly based on risk measures like *VaR* (namely the *value-at-risk*) and *TailVaR*).

Several features of stochastic models in both life and nonlife insurance are described in [11]. Longevity risk is analyzed, for example, by Olivieri [12] (*see also Stochastic Control for Insurance Companies; Estimation of Mortality Rates from Insurance Data*).

ERMANNNO PITACCO

Insurance Pricing/Nonlife

The fundamental principles concerning insurance pricing in the nonlife area are essentially similar to the principles that are applied to price life insurance policies, but often with different emphasis on the constituent parts (e.g., correlation of risks, temporal longevity of risks, and effects of the capital market). Certain distinct characteristics of nonlife insurance policies suggest modifications of original techniques and have inspired creation of new approaches.

The essentials of pricing both life and nonlife policies can be summarized in the (oversimplified) statement that price equals the expected present value of the loss(es) times a load for expenses, times a load for profit, and times a load for risk bearing (see equation (1)).

An important area in which nonlife and life insurance pricing differ is the significance of regulatory intervention and social influences on pricing. Since certain nonlife policies are mandatory for purchase (e.g., individual automobile insurance, workers compensation), and others are required by contractual obligations (e.g., homeowners insurance on mortgaged homes, comprehensive collision insurance on financed automobiles), there is substantial support theoretically and socially for stronger regulatory control of pricing in nonlife insurance. Most regulatory environments impose the conditions that rates (or premium) cannot be inadequate (to assure solvency), excessive (to prevent excessive profits), or unfairly discriminatory (for social equity), and these considerations must be incorporated into prices.

One other major distinction between life and nonlife pricing is that nonlife risks usually have much shorter contract duration than life or annuity contracts. For example, an important nonlife insurance line, automobile insurance, is usually offered with coverage of 6 months or 1 year. Consequently, the effects of economic factors can differ in nonlife insurance pricing, where insurers often need to account for economic fluctuations much more aggressively than they do in pricing life insurance policies, which may have durations measured in decades.

The shorter duration of nonlife risk exposure means that long-term returns on assets cannot “bail you out” of short-term pricing errors. Thus, in nonlife pricing, financial approaches seem to be more appealing to insurers than some of the traditional supply

side actuarial methods that dominate the life market. Financial approaches are even used in regulatory hearings concerning what constitutes a “fair rate of return” for insurers (*cf.* [1]). Well-known financial pricing models such as the capital asset pricing model (CAPM) (*see Axiomatic Models of Perceived Risk*) and option pricing models have been introduced and tailored for use in pricing nonlife insurance products. As a result, the integration of financial pricing and traditional actuarial pricing has been an ever growing trend in both theory and practice.

In this article, both actuarial approaches and financial pricing methods are discussed for pricing nonlife insurance products. General (actuarial) ratemaking methods are first introduced, followed by a brief summary of important premium principles and the properties of these principles. Credibility theory, one of the core concepts in nonlife actuarial science, is then discussed. Lastly, we describe various financial pricing models and conclude with a comment on the integration of traditional insurance pricing and financial pricing.

General Ratemaking

The general framework for pricing risk in both life and nonlife settings can be illustrated *via* the formula

$$P = E \left[\sum_{i=1}^N L_i V^{T_i} \right] (1 + k_1)(1 + k_2)(1 + k_3) \quad (1)$$

where

L_i : severity (in dollars) of the i th claim,

N : number of claims incurred during the policy period,

$V : \frac{1}{1+r}$, the discount rate based on interest rate r ,

T_i : time until i th claim during policy coverage period,

k_1 : expense load (underwriting, marketing, claims adjusting and administration, commissions, taxes, general operating expenses),

k_2 : profit load (to obtain a “fair” rate of return), and

k_3 : load for risk bearing uncertainty.

Note that in life insurance, $N \equiv 1$, L is fixed at the policy face value, and T (and possibly V) is a random variable. In nonlife insurance, one can have multiple claims of difference sizes on the same policy, so N , L_i , V , and T_i can all be considered as random variables.

Manual Rates

“Manual rates” is the name for rates (or prices) determined using basic rating tables that instruct insurers how to price different classes of risks for a particular insurance product with a certain coverage. From these tables, one obtains a numerical value (say dollars to charge per \$1000 of potential coverage), which can be applied to supply a price for a designated risk within the class of risks covered by the table. Therefore, they are used to price risks in a homogeneous group of exposures, and not to tailor the premium to any specific individual. Two basic methods are used in developing manual rates: the pure premium method and the loss ratio method [2]. The pure premium method determines an indicated rate based on the exposure and expected loss. Mathematically, we have

$$R = \frac{P + F}{1 - V - Q} \quad (2)$$

where R is the indicated rate per unit of exposure, P is the expected loss per unit of exposure (pure premium), F is the fixed expense per exposure, V is the variable expense factor, and Q is a profit and contingency factor. Essentially, this formula says that the rate must be sufficient to pay the expected losses plus fixed expenses after allowing for variable expenses and required profits.

The loss ratio method is a premium adjustment method rather than a premium setting method. It determines the indicated rate changes based on the current rate (R_0) through multiplying R_0 by an adjustment factor (A). This adjustment factor (A) is defined as the ratio of the experience loss ratio (Y) to a prespecified target loss ratio (T). Mathematically, we have

$$R = AR_0 \quad (3)$$

where R_0 is the current rate, $A = \frac{Y}{T}$, $Y = \frac{L}{(R_0)(E)}$, $T = \frac{1-V-Q}{1+M}$, L is the experience losses, E is the earned exposure for the experience period, V is the premium-related expense factor, Q is the profit and contingency factor, and M is the ratio of non-premium-related expenses to losses. It is clear that, by construction, the loss ratio method is not applicable to new lines of business, where a current rate is unavailable. However, it allows the insurer to update last period's rates to obtain new rates for the next

period. Brockett and Witt [3] show that when current prices are set by a regression methodology based on past losses, and the loss ratio method is used to adjust prices, then an autoregressive series is obtained, thus partially explaining insurance pricing cycles. Although the pure premium method and the loss ratio method are constructed from different perspectives, it can be shown that the two methods are identical and would produce the same rates given the same data (for more mathematical details, see [2]).

Individual Risk Rating

Individual risks are usually rated by making changes to manual rates to account for individual characteristics. A basic approach is through the use of a credibility formula, where individual loss experience is incorporated with expected losses for the corresponding risk class to obtain a refined rate (this idea will be detailed in a later subsection). Two basic rating schemes are employed in individual risk rating, namely, prospective rating and retrospective rating [2].

Prospective rating uses experience of past losses to determine the future rate. An important type of prospective rating is experience rating, where the rate for a future period is determined using a weighted combination of experienced losses and expected losses, both from a prior period. Retrospective rating, on the other hand, uses current period experience to obtain the rate for the same period. The rate is also determined by combining individual experience and exposure, in which aspect it works essentially in the same way as experience rating. Thus, with a retrospective rating plan, a certain amount of premium can be rebated back if loss experience during this period is very good, whereas with experience rating, good loss experience affects future premiums. It should be noted that in both of the rating schemes, insurers need to choose an appropriate experience period to balance experience and standard expected rates. Besides the above-mentioned methods, another somewhat different method for individual risk rating is schedule rating. As a type of prospective rating, it makes adjustments to manual rates to reflect characteristics of individual risks that may affect future losses. Unlike other individual risk rating methods, it does not involve individual loss experience to achieve

this goal, but rather directly factors in characteristics known to affect the likelihood of losses (e.g., a sprinkler system in a warehouse may result in a multiplicative factor less than one being applied to the pertinent manual table rates).

Classification

Prices in nonlife insurance are usually set for a group of exposures having similar risk characteristics when individual experience is not credible enough, or it is not cost effective to rate or price the individual risk by itself. Being an integral part of the pricing process, this process (called *classification*) of dividing prospective risks into homogeneous groups is of importance in its own right and is the subject of legal, regulatory, and social constraints. More specifically, by classification, individual risks are grouped together and the same premium is charged to each member of the entire group (the premium will, however, be different for the same coverage for different groups). Grouping is based on multidimensional group characteristics that reflect different insurance costs, including difference in losses, expenses, investment income, and risk (deviation from the expected value). These group characteristics are usually called *rating variables* and they may differ across lines of insurance (e.g., in automobile insurance, the common rating variables are age, gender, and marital status). Various criteria are used to select these rating variables, e.g., actuarial criteria, operational criteria, and social criteria [2]. As competition among insurers becomes more intensive, insurers tend to constantly refine their choice of rating variables and classification to ensure availability of coverage and avoid adverse selection. For example, insurance credit scores based on the credit history of the individual being classified are now used in many automobile and homeowners insurance rating plans, as this variable has been found to be extremely predictive of losses and nonoverlapping with other traditional rating variables (cf. [4]).

Premium Principles

Traditional Premium Principles

(The concepts of premium principles (see **Premium Calculation and Insurance Pricing; Risk Measures**

and Economic Capital for (Re)insurers) are developed in great detail in [5], from which this section is drawn heavily. Interested readers are referred to [5] for more details.)

Certain traditional principles are employed in the process of premium calculation. Among the most commonly used ones are the expected value principle, the maximal loss principle, the variance principle, the standard deviation principle, the semivariance principle, the mean value principle, the zero utility principle, the Swiss premium calculation principle, the Esscher principle, and the Orlicz principle. These principles differ in the rationale they use to assign a (numeric) premium to a given risk. Each of them requires a certain potentially different level of knowledge of the risk distribution and may be appropriate only in certain situations. For the following discussion, denote the risk (random variable) as X and the premium for the risk X as $\Pi(X)$. Table 1 gives a brief description of the above-mentioned premium principles.

Properties of Premium Principles

In designing premium principles, a set of properties are usually desired based on intuitive grounds. We first introduce commonly discussed properties and then examine whether they are satisfied by the premium principles presented in Table 1 (note that many of the properties can be generalized to allow for more complicated considerations).

- Property 1* (Mean value exceeding property): The premium should exceed the expected claim, i.e., $\Pi(X) > E(X)$.
- Property 2.1* (Additivity): For independent risks X_1 and X_2 , a premium principle is additive if $\Pi(X_1 + X_2) = \Pi(X_1) + \Pi(X_2)$.
- Property 2.2* (Subadditivity): For independent risks X_1 and X_2 , a premium principle is subadditive if $\Pi(X_1 + X_2) \leq \Pi(X_1) + \Pi(X_2)$. Note that additivity implies subadditivity.
- Property 3.1* (Translation invariance): A premium principle is translation invariant if $\Pi(X + c) = \Pi(X) + c$ for any constant c .
- Property 3.2* (Subtranslativity): A premium principle is subtranslative if $\Pi(X + c) \leq$

Table 1 Basic premium principles

Name of premium principle	Mathematical definition	Description
Expected value principle	$\Pi(X) = (1 + \lambda)E(X)$	$E(X)$ is the expected value of risk X . λ is a positive safety loading. If $\lambda = 0$, it is called <i>net premium principle</i> .
Maximal loss principle	$\Pi(X) = pE(X) + (1 - p)\text{Max}(X)$	$\text{Max}(X)$ denotes the largest possible value of X . (This value only exists for bounded risks. However, this principle can be generalized.)
Variance principle	$\Pi(X) = E(X) + \lambda\text{Var}(X)$	$\text{Var}(X)$ is the variance of risk X . λ is a positive safety loading.
Standard deviation principle	$\Pi(X) = E(X) + \lambda\text{Stddev}(X)$	$\text{Stddev}(X)$ is the standard deviation of risk X . λ is a positive safety loading.
Semivariance principle	$\Pi(X) = E(X) + \lambda\text{PosVar}(X)$	$\text{Var}(X)$ is decomposed into $\text{PosVar}(X)$ (positive variance component) and $\text{NegVar}(X)$ (negative variance component) to capture the direction of deviation from mean. λ is a positive safety loading.
Mean value principle	$\Pi(X, f)$ solves $f(\Pi) = E(f(X))$	f is a continuous and strictly monotonic function on the domain of X (This is essentially to find the certainty equivalent of X if f is an utility function)
Zero utility principle	$\Pi(X, u)$ solves $E[u(\Pi - X)] = 0$	u is an utility function, which satisfies certain properties: u is continuous, nondecreasing ($u'(x) \geq 0$), and concave ($u''(x) < 0$), $u(0) = 0$ and $u'(0) = 1$. It is called <i>zero utility</i> since the premium is set such that accepting the risk for premium Π gives the insurer the same utility as not accepting the risk.
Swiss premium calculation principle	$\Pi(X, f, z)$ solves $E[f(X - z\Pi)] = f[(1 - z)\Pi]$	f is a continuous and strictly monotonic function. z is in $[0, 1]$. (If $f' \geq 0$, $f'' < 0$, $z = 1$, $f(0) = 0$, $f'(0) = 1$, then it returns a zero utility principle. If $z = 0$ then it returns a mean value principle.)
Esscher principle	$\Pi(X) = \frac{E(Xe^{\alpha X})}{E(e^{\alpha X})}$	$\alpha > 0$
Orlicz principle	$\Pi(X, f)$ solves $E\left[f\left(\frac{X}{\Pi}\right)\right] = f(1)$	$f' > 0$, $f'' > 0$

$\Pi(X) + c$ for any constant c . Note that translativity and subtranslativity are essentially identical.

Property 4 (Iterativity): A premium principle is iterative if $\Pi(X) = \Pi(\Pi(X|Y))$, where Y is the risk parameter (random variable) ($\Pi(X|Y)$ can be considered as a new risk based on Y).

Property 5 (Homogeneity): A premium principle is homogeneous if $\Pi(cX) = c\Pi(X)$ for any constant c . Moreover, it is called *positive homogenous* if the

above relation only holds for $c > 0$. It is called *symmetric* if the above relation only holds for $c = -1$.

Property 6 (Multiplicativity): For independent risks X and Y , a premium principle is multiplicative if $\Pi(XY) = \Pi(X)\Pi(Y)$.

Next, we examine each premium principle for these properties. A summary is presented in Table 2. From Table 2, we can see that some of the properties are more restrictive than others in the sense that

Table 2 Examination of properties of premium principles

Name	Mean value exceeding	Additivity	Subadditivity	Translativity (subtranslativity)	Iterativity	Homogeneity	Multiplicativity
Expected value principle	Yes	Yes	Yes	Yes, only when $\lambda = 0$ (net premium principle) Yes	Yes, only when $\lambda = 0$ (net premium principle) Yes, only when $p = 0$	Yes	Yes
Maximal loss principle	Yes (when $p \neq 1$)	Yes	Yes	Yes	Yes, only when $p = 0$	Yes, when $c > 0$ (positive homogeneous)	Yes, only when $p = 1$ (net premium principle) No
Variance principle	Yes	Yes	Yes	Yes	No	Yes, only when $\lambda = 0$ (net premium principle) Yes, when $c > 0$	No
Standard deviation principle	Yes	No	Yes	Yes	No	(positive homogeneous)	No
Semivariance principle	Yes	No	No	Yes	No	Yes, only when $\lambda = 0$ (net premium principle)	No
Mean value principle	Yes (when f is continuous, strictly increasing, and convex)	Yes, only when $f(X) = X$ (net premium principle) or $f(X) = \exp(\alpha X)$ (exponential principle)	Yes for positive subadditivity ($X, Y > 0$), only when f is continuous and strictly increasing, f' is concave	Yes, only when $f(X) = X$ (net premium principle) or $f(X) = \exp(\alpha X)$ (exponential principle)	Yes	Yes, under certain conditions on $f(x)$ (see [5] for details)	Yes, only when $f(X) = X$ (net premium principle)
Zero utility principle	Yes	Yes, only when $u(X) = X$ (net premium principle) or $u(X) = \exp(\alpha X)$ (exponential principle)	Yes, only when $u(X) = X$ (net premium principle) or $u(X) = \exp(\alpha X)$ (exponential principle)	Yes	Yes, only when $u(X)$ is linear or exponential	Yes, when $c > 0$ (positive homogeneous) under certain conditions on $u(x)$ (see [5] for details)	Yes, only when $u(X) = X$ (net premium principle)

(continued overleaf)

Table 2 (continued)

Name	Mean value exceeding	Additivity	Subadditivity	Translativity (subtranslativity)	Iterativity	Homogeneity	Multiplicativity
Swiss premium calculation principle	Yes (when f is continuous, strictly increasing, and convex)	Yes, only when $f(X) = X$ (net premium principle) or $f(X) = \exp(\alpha X)$ (exponential principle)	Yes, for positive subadditivity only when reduced to mean value principle and satisfy conditions specified for mean value principle	Yes, only when $f(X) = X$ (net premium principle) or $f(X) = \exp(\alpha X)$ (exponential principle)	Yes, only when it returns to mean value principle or zero utility principle with linear or exponential $u(X)$	Yes, under certain conditions on $f(x)$ (see [5] for details)	Yes, only when $f(X) = X$ (net premium principle)
Esscher principle	Yes, when $\alpha > 0$	Yes	Yes	Yes	Yes, only when $\alpha = 0$ (net premium principle)	Yes, when $c > 0$ (positive homogeneous) and when $\alpha = 0$ (net premium principle)	Yes, only when $\alpha = 0$ (net premium principle)
Orlicz principle	Yes	Yes, only when f is linear (net premium principle)	Yes, only when f is linear (net premium principle)	Yes, only when f is linear (net premium principle)	Yes, only when $f(x) = x^{1+\alpha}$, f'' is continuous	Yes, when $c > 0$ (positive homogeneous)	Yes, only when f is linear (net premium principle) (certain conditions of f)

fewer principles satisfy these properties. In practice, however, it is not necessary for the premium principle adopted to possess all the listed properties. The choice of premium principle will depend on the specific rating scenario.

Wang's Class of Premium Principles

Premium principles introduced in the last subsection are mostly motivated by the net premium concept ($\Pi(X) = E(X)$) or utility theory (see **Optimal Risk-Sharing and Deductibles in Insurance; Risk Measures and Economic Capital for (Re-)insurers; Mathematics of Risk and Reliability; A Select History; Clinical Dose–Response Assessment**). Another way to motivate the design of premium principles is to first delineate the desired properties and then search for the class of rules that satisfy these properties. An increasingly important class of premium principles named *Wang's class of premium principles* are motivated in this fashion. Wang [6] makes use of the survival function $S(x)$ ($S(x) = \Pr(X > x) = 1 - F(x)$, where $F(x)$ is the distribution function of X) to describe the layer premiums. Premium principles are desired to preserve the ordering of risks in the first order and the second order (or, “stochastic dominance preservative” (see **Risk Attitude**)) and to be additive for comonotonic risks (or, “comonotonic additive” (see **Credit Risk Models**)). Comonotonic risks refer to risks X_1 and X_2 that can both be represented as nondecreasing functions of risk Z , or mathematically, $X_1 = f_1(Z)$ and $X_2 = f_2(Z)$, where f_1 and f_2 are nondecreasing functions. The desired class of premium principles that possess the above two properties are obtained by transforming the survival function using a distortion function g , i.e., $g[S(x)]$, where g satisfies certain conditions as specified in [6] (e.g., g can be a utility function with $g(0) = 0$ and $g(1) = 1$). The premium principle is then defined as

$$\Pi(X) = \int_0^\infty g[S(x)] dx \quad (4)$$

This class of premium principles satisfies basic properties (e.g., mean value exceeding, homogeneity, and additivity) as well as the two particular properties emphasized above. The notion of a distortion function underlying the derivation of this class of premium principles has also been employed extensively in

developing risk measures and in other insurance applications.

Credibility of Data in Determining Rates

The idea behind credibility theory dates back to Mowbray in 1914 [7]. It is said to be “the casualty actuaries’ (see **Reinsurance**) most important and enduring contribution to casualty actuarial science” [8, p. 3]. The goal is to construct a method that incorporates individual level data together with standard or industry level data in a manner that allows for the individual data not to be unduly influential on the final price unless the amount of individual data is large enough for it to become “credible”. It is the quantification of this idea that constitutes the area of credibility theory.

Credibility theory has seen wide application in insurance pricing areas such as experience rating and ratemaking for new risks. It recognizes both the reliability of some form of class estimate and the additional value of heterogeneous individual risk experience, both of which together constitute an estimate for expected losses of the individual risk. Under credibility theory, a credibility factor z is assigned to the individual data, while a factor $(1 - z)$ is assigned to the class estimate. Mathematically, a credibility formula can be written as

$$C = z\hat{m} + (1 - z)M \quad (5)$$

where C is the premium or the best estimate of expected future loss for the individual risk, $\hat{m}$ represents the individual loss experience, M is the class or industry level estimate of loss or a prior estimate of loss, and z is the credibility factor. A higher credibility factor indicates that the particular individual data examined has a higher degree of accuracy in predicting future losses and thus is more important in premium calculation, i.e., more “credible”. For example, insurers are usually more confident in using experience of an individual risk with a large exposure to derive its premium than in the contrary case.

This rating method gives rise to the issue of estimating the credibility factor in order to come up with a final combined estimate for the individual risk. A natural way to decide credibility is to associate it with the variation of individual risk experience, i.e., individual data is more valuable when risk experience is relatively stable. To formalize the

theoretical construction and practice of credibility theory, two major branches of research were in place, namely, the limited fluctuation approach first proposed by Mowbray [7] and the greatest accuracy approach by Bühlmann [9, 10].

Recently, credibility theory has been developed for multidimensional cases and allows for nonlinear structures [11]. Moreover, the underlying connection between credibility formulae and empirical Bayesian (*see Risk in Credit Granting and Lending Decisions: Credit Scoring; Repairable Systems Reliability; Microarray Analysis*) approaches has been established. Advancement in modern Bayesian theory and computation will further facilitate the development and utilization of credibility theory (*cf.* [12, 13]).

Limited Fluctuation Approach

The main focus of limited fluctuation approach is to restrict the deviation of individual loss experience from the true underlying individual risk to grant full credibility to the individual risk data. More specifically, under certain assumptions on the losses, this method arrives at a required number of observations (e.g., exposure units) from the particular risk. Assume that we have, for the particular individual risk, independently identically distributed (i.i.d.) annual claim amounts $X_i, i = 1, \dots, N$. X_i 's have mean $\mu(\theta)$ and variance $\sigma^2(\theta)$, where θ is a (nonstochastic) parameter characterizing this particular individual risk. Let the individual estimate in the credibility formula be the average of the claims, i.e., $\hat{m}(X) = \frac{1}{N} \sum_{i=1}^N X_i$. Under limited fluctuation approach, we would like the difference between $\hat{m}$ (the estimate from individual data) and μ (the true mean of this individual risk) to be less than a chosen percentage (k) of μ with a large probability, or mathematically,

$$\Pr[|\hat{m}(X) - \mu(\theta)| \leq k\mu(\theta)] \geq p \quad (6)$$

where k is a positive small value and $0 < p < 1$, p is close to 1. Under Normal approximation, we derive

$$N \geq \frac{z_{(1+p)/2}^2 \sigma^2}{k^2 \mu^2} \quad (7)$$

where $z_{(1+p)/2}$ is the $(1+p)/2$ fractile of a standard normal distribution. The percentage k and confidence level p are parameters to be determined by the insurer. Formula (7) says that full credibility is

granted to the individual risk data when the condition on N is satisfied. Partial credibility can also be calculated by requiring the variance of component $z\hat{m}$ in credibility formula (5) to be less than the variance of individual estimate $\hat{m}$ when full credibility is warranted, through adjusting down the credibility factor z from 1.

The above procedure shows that the limited fluctuation approach is easy to implement and flexible in the sense that insurers can freely select parameters based on the specific rating scenario. However, this approach is subject to several limitations. Firstly, the case of full credibility is stressed by determining a large enough number of previous claims N . However, this approach does not provide solid theoretical justification of the decision of partial credibility factor, making it less useful in many situations when full credibility cannot be reasonably obtained [11]. Secondly, this approach fails to fully account for the quality of the class estimate M (treated as a constant). When the class estimate cannot accurately capture the individual risk, higher credibility should naturally be assigned to individual data, even when N is relatively small [2].

Greatest Accuracy Approach

Greatest accuracy approach (least-squares approach) was proposed initially by Bailey [14] and gained popularity through Bühlmann's work [9, 10]. Bühlmann suggested a nonparametric approach to come up with the credibility formula [9]. Suppose we have conditionally independent and identically distributed (i.i.d.) (given θ , the individual risk parameter, which is drawn from the parameter set Θ) annual claim amounts $X_1, \dots, X_N$ with mean $\mu(\theta)$ and variance $\sigma^2(\theta)$. The individual estimator $\hat{m}(X)$ is taken to be the average of the claims $\hat{m}(X) = \frac{1}{N} \sum_{i=1}^N X_i$. The idea of the (linear) least-squares approach is to find an estimator in the form of a linear function of $\hat{m}(X)$, which minimizes the expected squared error in estimating the premium for the individual risk. We arrive at the credibility formula (5) with

$$M = E\mu(\theta) \quad (8)$$

$$\hat{m} = \frac{1}{N} \sum_{i=1}^N X_i \quad (9)$$

and

$$z = \frac{N}{N + K} \quad (10)$$

$$K = \frac{E\sigma^2(\theta)}{\text{var}\mu(\theta)} \quad (11)$$

where M is the overall mean claim and $\hat{m}$ is the mean of the individual claim data for this particular risk. We can see that the credibility factor z as in equation (10) depends on the variation of the underlying risk premium $\text{var}\mu(\theta)$, variation of the individual claim observations $E\sigma^2(\theta)$, and the number of observations (N). Intuitively, when class estimate is more volatile or we have a larger amount of individual loss information, higher credibility will be assigned to the individual loss experience. When individual loss experience is more volatile, less credibility is assigned to it. In this way, the greatest accuracy approach provides both a theoretically justified and an intuitive way to combine individual loss data and the class estimate, taking into account their respective quality.

A further development of this approach considers different amount of risk exposure. In this case, we consider X_i 's as loss ratios (total amount of claims for year i divided by expected amount of claims (exposure) for year i) and the variance of X_i 's is allowed to depend on the risk exposure p_i for year i . The credibility formula takes the form of equation (5) with

$$M = E\mu(\theta) \quad (12)$$

$$\hat{m} = \frac{\sum_{i=1}^N p_i X_i}{\sum_{i=1}^N p_i} \quad (13)$$

and

$$z = \frac{\sum_{i=1}^N p_i}{\sum_{i=1}^N p_i + K} \quad (14)$$

$$K = \frac{E\sigma^2(\theta)}{\text{var}\mu(\theta)} \quad (15)$$

where p_i is the exposure (or size of the risk) for year i . We can see that the credibility factor z as defined in equation (14) depends on the total exposure for the risk. Larger exposure warrants higher credibility. This model is known as the *Bühlmann–Straub model* [15].

Financial Pricing of Insurance

As described in the introduction, financial pricing methods are widely used in nonlife insurance. In essence, insurance products can be viewed as a contingent future performance contract, where the future performance involves financial obligations with contingent claim payments. The trigger for the contingent claims is a qualified loss on the underlying risk event, such as loss owing to natural disasters, liability, etc. Thus, insurance pricing models can be constructed using pricing models for contingent claim contracts from the finance literature. These models are detailed below. (For a more complete summary of this topic, see [16].)

Insurance CAPM

The insurance CAPM views an insurance policy as a standard financial contract (e.g., a debt contract) and follows the rationale of the well-known CAPM. Papers by Fairley [17] and Hill [18] are among the first to discuss using the CAPM to address investment income and determine fair profit rates for property-liability insurers. The idea of the insurance CAPM is illustrated in a simple model that follows (notations here basically follow [19]). The insurer's net income is modeled as the sum of investment income and underwriting profit.

$$Y = I + \pi_p = r_A A + r_p P \quad (16)$$

where Y is net income, I is investment income, π_p is underwriting profit, r_A is (stochastic) return on assets, A is assets, r_p is (stochastic) return on underwriting, and P is insurance premium. On the basis of this setup, we can obtain a representation of the return on equity (ROE) as

$$r_E \left(= \frac{Y}{E} \right) = r_A + s(r_A k + r_p) \quad (17)$$

where r_E is the ROE, E is the equity, $s = \frac{P}{E}$ is the premium to surplus ratio, and $k = \frac{L}{P}$ is the funds generating factor (L is the liabilities and $L + E = A$).

Following the standard CAPM, expected return on asset i is modeled as risk-free rate plus expected individual risk premium for asset i , and expected individual risk premium is obtained by applying the beta coefficient for asset i to the expected market risk premium. Mathematically, we have

$$E(r_i) = r_f + \beta_i(E(r_m) - r_f) \quad (18)$$

where r_i is the (stochastic) return on asset i , r_f is the risk-free rate, r_m is the (stochastic) market return, and $\beta_i = \frac{\text{COV}(r_i, r_m)}{\text{var}(r_m)}$ is the beta coefficient of asset i .

To derive the insurance CAPM (i.e., the formula for calculating expected underwriting return), we first derive the underwriting beta as $\beta_p = \frac{\text{COV}(r_p, r_m)}{\text{var}(r_m)}$. Then by multiplying both sides of equation (17) with r_m and taking the covariance, we obtain, according to the formula for beta coefficients,

$$\beta_E = (1 + ks)\beta_A + s\beta_p \quad (19)$$

where β_E is the equity beta coefficient and β_A is the asset beta coefficient. Note that expected ROE, $E(r_E)$, can be derived by the CAPM equation (18) or by taking the expectation of equation (17). The resulting expressions from the above two approaches have to be equal. Thus by equating the two, we derive the insurance CAPM as

$$E(r_p) = -kr_f + \beta_p(E(r_m) - r_f) \quad (20)$$

The above calculation shows how an insurance policy is priced in the traditional CAPM framework. It is worth noting that instead of a positive risk-free return component (r_f) as in standard CAPM, the corresponding term in the insurance CAPM equation (20) has a negative coefficient, which stands for the part of rate rewarded back to the policyholders since the premium they paid at the beginning was used by the insurer to generate investment return for approximately k periods.

Despite its parsimony, the insurance CAPM is not likely to be a good candidate for use in practice. Besides general criticism that the CAPM has received (such as the insufficiency of using beta coefficients to explain returns [20]), other concerns have been raised for the insurance CAPM. These concerns include the use of fund generating factor, assumption of no bankruptcy, assumption of a constant interest rate, and estimation accuracy of underwriting beta [19].

Discounted Cash Flow Models

An alternative to the CAPM is the widely used discounted cash flow model (see **Credit Risk Models; Solvency**), which models price (present value) as a stream of future cash flows discounted at an appropriate interest rate. A simple version (in the discrete case) of this model in the context of insurance is presented below to illustrate the idea [19]. Assume a two period model with $t = 0, 1$. Premium is paid at $t = 0$ and loss payment is made at $t = 1$. Thus, according to the discounted cash flow model, premium is calculated as loss payment discounted by nominal interest rate

$$\Pi = \frac{L}{(1+r)} = \frac{L_0(1+\pi)}{(1+i)(1+r_r)} \quad (21)$$

where Π is premium, L is the value of promised loss payment at $t = 1$, L_0 is the present value of promised loss payment, π is the insurance inflation rate, r is the discount rate which can be decomposed into i , general inflation rate, and r_r , real interest rate. More realistic models taking into account other important cash flows of insurance companies (e.g., investment income, equity capital, tax payment) are built in a similar but much more complicated fashion (for example, see [21]). Discounted cash flow models have also been developed in the continuous-time setting. One class of these models are based on arbitrage pricing theory (APT), which is also a major asset pricing method in finance (for example, see [22]).

Option Pricing Models

The contingent nature of insurance claim payments suggests viewing insurance policies in the context of financial derivative contracts, e.g., options. The no-arbitrage pricing framework originally established for pricing derivatives can be adopted for nonlife insurance pricing. A simple description of the method (in the continuous case) is sketched below. Under this method, assets and liabilities are assumed to follow stochastic processes (e.g., geometric Brownian motion (see **Risk-Neutral Pricing; Importance and Relevance; Default Correlation**)). Thus, the basic mathematical representation for the asset process is

$$dA_t = r_A A_t dt + \sigma_A A_t dW_{tA} \quad (22)$$

and for the liability process is

$$dL_t = r_L L_t dt + \sigma_L L_t dW_{tL} \quad (23)$$

where A_t is assets, L_t is liabilities, r_A and r_L are drifts for assets and liabilities respectively, σ_A and σ_L are volatilities for assets and liabilities respectively, and W_{tA} and W_{tL} are standard Brownian motions. Built upon the underlying stochastic processes, characteristics of various contingent claims on the insurance companies can be captured by modeling them as put–call options, and premium (or other value of interest) can then be found by standard mathematical finance techniques (e.g., Black–Scholes formula [23] (*see Equity-Linked Life Insurance; Statistical Arbitrage; Asset–Liability Management for Life Insurers; Risk-Neutral Pricing: Importance and Relevance; Credit Scoring via Altman Z-Score; Statistical Arbitrage*)).

Direct use of the above model is limited in practice owing to the imposed restrictions, e.g., the use of European options. A few special cases where this model is suitable, such as premium calculation for the guaranty fund, are listed in Cummins [19]. However, this baseline model can be extended in many dimensions. For example, multiple liability processes can be considered, since many insurers write multiple lines of business rather than just offer a single product. Exotic options rather than standard European options can be used to model the underlying insurance processes.

Option pricing methods are considered especially useful in pricing catastrophic risks (e.g., earthquake, hurricane). Because of the unique nature of catastrophic risks (e.g., extremely large losses, high loss correlations), insurers seek capital market to finance their products. As a result, catastrophic bonds, futures, and options (e.g., PCS catastrophic insurance options (*see Actuary; Operational Risk Modeling*)) introduced by Chicago Board of Trade (CBOT)) are created to handle these risks. The potential value of using option pricing methods in this particular area is thus self-evident (*cf.* [24]).

In summary, the introduction of financial pricing methods have undoubtedly provided insurers with a much larger and potentially more effective toolkit for pricing nonlife insurance risks. However, limitations do exist in the current insurance financial methods and many areas in finance are yet to be explored.

Integration of Financial Pricing and Insurance Pricing

In a broad sense, insurance pricing and financial pricing are integrated in a no-arbitrage pricing framework. As discussed extensively in mathematical finance theory and applications, no-arbitrage pricing finds the expectation of the discounted value of the contingent claim (e.g., loss payments) under the risk neutral measure, i.e., the probability measure that makes the underlying stochastic process a martingale. Under this risk neutral measure, adverse events are assigned higher weights than under the original physical measure. Thus, the risk neutral measure incorporates the idea of safety loading in insurance pricing [25]. In traditional financial economics, this type of pricing scheme works well since the financial market is often considered as a complete market and thus a replicating portfolio can be formed to follow the rationale of Black and Scholes [23].

When this idea is applied to the field of insurance, however, a major challenge emerges: the insurance market is oftentimes illiquid and incomplete, since many of the underlying risks are nontradable and indivisible. As a result, it is often impossible to find a unique risk neutral measure. A method proposed for pricing in an incomplete market is “indifference pricing” [26]. The idea is to maximize expected utilities with and without writing the risk at premium Π , through which a value of Π can be obtained such that the insurer is indifferent between writing the policy and not doing so. This process incorporates investor’s risk preference (captured by the utility function), which cannot be eliminated as in the traditional setting owing to market incompleteness.

However, when we are able to find appropriate risk neutral measures and price insurance claims in the no-arbitrage framework, we see that traditional premium principles (e.g., expected value principle and Esscher principle) derived from actuarial approaches can be recovered by the proper choice of risk neutral measures, which validates the interrelation between these two approaches [25].

The interactions between the areas of insurance and finance have greatly advanced the development of pricing techniques in insurance. Inventions of new instrument products in this process may potentially complete the market and thus make standard finance models more accessible and applicable in insurance pricing. Continuous unification of insurance pricing

and financial pricing is an inevitable trend that will bring new insights and provide benefits to both fields.

JING AI AND PATRICK L. BROCKETT

Integration of Risk Types

Traditionally, financial institutions manage and therefore, also measure their risk in different departments, usually the credit, marketing, and operations department. The corresponding risks are credit risk, market risk, and operational risk (OR). Some institutions also measure other risks like business risk, liquidity risk, private equity risk and environmental risk, among others. On the other hand, these institutions need an aggregate unified view of their risk positions. Therefore, some procedures to integrate those risks are in place. The simplest one is, assuming that in each type the risk is finally measured in some monetary unit, like economic capital, to add all these figures to obtain an overall monetary risk measure. However, this totally ignores the concept of diversification across risk types. To obtain a more accurate picture of the integrated risk, more sophisticated methods are necessary. The two basic approaches are the so-called bottom-up and top-down [1–3]. Both are possible since risk measurement follows the same basic route in all risk types. This will be explained in the following section on the common features of risk measurement, whereas in sections titled “Top-Down Approach” and “Bottom-Up Approach” the two integration approaches are described in greater detail. Since the bottom-up approach is much more challenging and usually only achieved for specific departments of a bank, it is only briefly commented upon. Our focus is not on the risk models in the different risk types. Hence, the credit, market, or operational risk models are not covered in detail, but emphasis is more on their potential integration. For the different risks, we the reader may refer to more specific articles in this encyclopedia or in the cited literature.

Common Features of Risk Measurement

The basic common features can be described by means of the loss variable denoted by $L_{\text{type}}(\omega)$, the loss in risk type, $\text{type} \in \{\text{market}, \text{credit}, \text{operational} \dots\}$ (cf. [4, 5]) in state of the world $\omega \in \Omega$. It is modeled on an underlying probability space $(\Omega, \mathcal{A}, P)$. Then we usually have

$$L_{\text{type}}(\omega) = f_{\text{type}}(\vec{X}(\omega)) \quad (1)$$

Here the loss variable L can refer to a single transaction, a subunit of the bank, or the bank’s entire loss distribution in risk type “type”. Here, we assume that the vector $\vec{X}$ consists of all factors used in any risk calculation and $f_{\text{type}}(\vec{x})$ gives the functional form of the change in value in risk type “type” in state of the factor $\vec{x}$. f can also be thought of as a valuation function; it only remains to specify the joint distribution of the vector $\vec{X}$.

Example

1. The so-called delta–gamma approach in market risk (as in [4, 6]) assumes a lognormal distributed X and takes a second-order approximation of the value function F , i.e., the loss is approximated by

$$L_{\text{market}}(\omega) = \Delta \cdot \vec{X}(\omega) + \vec{X}^T(\omega) \Gamma \cdot \vec{X}(\omega) \quad (2)$$

Here, Δ is the gradient of the value function of the position with respect to the underlying risk factors, i.e., the i th component

$$\Delta_i = \sum_{k=1}^K \Delta_{i,k} \quad (3)$$

where $\Delta_{i,k}$ is the sensitivity of transaction k to risk factor i . The matrix Γ denotes the second derivatives of the transactions with respect to the risk factors. The factors $\vec{X}$ are usually equities, Foreign Exchange (FX), interest rates, implied volatility, and other market variables.

2. In credit risk in a simple default mode (cf. [7, 8] or [9]), one would take

$$f_{\text{credit}}(\vec{x}) = \sum_{i=1}^m \mathbf{1}_{\{x_i \leq C_i\}} \quad (4)$$

and therefore

$$L_{\text{credit}}(\omega) = f_{\text{credit}}(\vec{X}(\omega)) = \sum_{i=1}^m \mathbf{1}_{\{X_i(\omega) \leq C_i\}} \quad (5)$$

A typical modeling assumption here is that the vector $\vec{X}$ represents the asset values of the counterparties.

3. OR (*cf.* [4, 5]) usually assumes an insurance-type loss distribution (*see* **Large Insurance Losses Distributions**)

$$L_{\text{OR}} = \sum_{i=1}^N S_i \quad (6)$$

where N is the number of events in a certain OR type and S stands for the severity of an event. There are many attempts to define and calibrate risk factors, often called *risk indicators*, $\vec{X}$ such that $N = N(\vec{X})$ and $S_i = S_i(\vec{X})$. However, this development is currently in a very preliminary stage and usually integration with OR is done by the copula version of the top-down approach.

Integration can now be done at different levels. A full integration means that the entire loss distribution is modeled as a function f_{total} of the entire vector of the risk factors. In this most challenging approach, the entire set of risk factors is integrated, as well as the valuation function f of the portfolio on this vector, i.e.,

$$L_{\text{total}}(\omega) = f_{\text{total}}(\vec{X}(\omega)) \quad (7)$$

Since the portfolio loss is always the sum of the losses in the individual transactions

$$L_{\text{type}} = \sum_{\text{all transactions}} L_{\text{type}}^{\text{transaction}} \quad (8)$$

this approach already requires an integration of the loss function on transaction level

$$L_{\text{total}}^{\text{transaction}}(\omega) = f_{\text{total}}^{\text{transaction}}(\vec{X}(\omega)) \quad (9)$$

Therefore, it is usually called a *bottom-up integration*. Top-down integration means that integration is carried out at the level of portfolio loss variables. Here the basic assumption is that the loss variables are additive.

Top-Down Approach

In the top-down approach, the financial institution measures the different risk types separately in different departments and systems. As a result, the loss distribution L_{type} is specified at the institution-wide level, but separately for each risk type. The total loss

distribution is then the distribution of the random variable

$$L_{\text{total}} = \sum_{\text{all types}} L_{\text{type}} \quad (10)$$

The associated function f_{total} is as such the sum of the f_{type} 's. An important feature of this approach is that the loss variable is additive in the risk types. Intuitively, this means that the total loss is always the sum of the losses due to credit risk, market risk, and other risks. One can therefore also refer to this as “additivity of risk types”. In the bottom-up approach, this additivity does not hold since the loss or change in value is a possible nonlinear function of the entire vector of risk drivers. Separation into credit and market risk is not possible in such a case.

Factor Approach

If the bank can identify the entire factor space $\vec{X}$ driving all risk types and specify the joint distribution, then the entire loss distribution is given by

$$L_{\text{total}}(\omega) = \sum_{\text{all types}} f_{\text{type}}(\vec{X}(\omega)) \quad (11)$$

In some cases, there might be risk factors that drive, for example, credit and market risks. In many cases, the factor spaces are modeled separately and the joint distribution of $\vec{X}$ is specified. Then often a copula approach (*cf.* [5, 10–12]) at the level of the factors is implemented. An obvious challenge in this approach is to minimize the number of factors.

Copula Approach

If the underlying factor vector $\vec{X}$ cannot be specified and only the marginal distributions of L_{type} for all risk types are known, the joint distribution of the vector

$$\vec{L} = (L_{\text{type}})_{\text{type} \in \{\text{all types}\}} \quad (12)$$

can be specified by the copula approach:

$$\vec{F}(\vec{l}) = C(F^{(1)}(l_1), \dots, F^{(m)}(l_m)) \quad (13)$$

where $\vec{F}$ is the distribution function of $\vec{L}$, C is the copula function, m is the number of risk types, and

$F^{(j)}$ is the distribution function for losses in risk type j , $j = 1, \dots, m$.

Example

Let us exhibit a concrete, realistic example from [1] for the integration of credit and market risks. The current mark-to-market of the bank equals 100 and the current credit exposure equals 10 000. The assumption on market risk is that the percentage change over 1 year is normally distributed with an annual volatility of 20% and mean zero. The 99% value-at-risk turns out to be 46.6. As a plausible credit loss distribution, the Vasicek distribution, which can be found in [13] or [14], with $p = EL = 0.003$ (30 basis points annual expected loss) and an asset correlation of $\rho = 12\%$ is used. The 99% percentile of the corresponding credit loss distribution minus the expected loss, that is, the economic capital for credit risk, is then 162.5.

In the traditional nonintegrated calculation, the overall “integrated” risk is just the sum of the two (i.e., 100% correlation is assumed). With a correlation assumption of 50% for the normal copula, there is around 10% reduction in economic capital. This is only a small benefit owing to diversification across risk types, since credit risk dominates in any case. If one changes the Mark-to-Market (MtM), the percentile, and also the correlation, one obtains the figures in Table 1. Here $\rho_{M,C}$ is the correlation in the normal copula between credit and market risks. Diversification benefit is the decrease in integrated risk compared to the simple addition of credit and market risks. Compare [1]: the largest benefit (28%) can be observed, if we have roughly equal risk capital for market and credit risks, market risk = 255, and credit risk = 206, and a small correlation $\rho_{M,C} = 0.3$.

Table 1 Examples of top-down integration

Percentile	$\rho_{M,C}$	MtM	Market risk	Diversification benefit (%)
0.99	0.5	100	46	10
0.99	0.3	500	230	25
0.995	0.5	100	51	7
0.995	0.3	500	255	28

Remarks

1. Traditionally, market risk in the trading area is measured at a 1- or 10-day value-at-risk (see **Equity-Linked Life Insurance; Credit Scoring via Altman Z-Score**) and credit-value-at-risk (see **Extreme Value Theory in Finance**), and OR usually on a 1-year horizon. For integration purposes, there are different ways to solve the problem with different time horizons. Since it is very difficult to consider credit risk at a shorter horizon, one usually tries to measure market risk on a 1-year horizon. As a compromise a 3-month horizon can also be taken for the integration.
2. The effect of dynamic portfolios whose modeling is a great challenge is currently ignored in the risk measurement models.

Bottom-Up Approach

Here, the change in value T_i of a transaction i is a function of the risk factors denoted by $\vec{x}$, the entire universe of risk factors. As a typical example, consider what is called *wrong-way exposure* in credit risk management (cf. [15]). Assume e.g., that the bank has bought a put on the Nikkei from a large Japanese bank, which carries a large weight in the Nikkei. As the Japanese bank deteriorates in credit quality, the Nikkei will drop in value, making the put more valuable. But at the same time, the probability that the Japanese bank will not fulfill its contingent payment (see **Actuary; Asset-Liability Management for Life Insurers; Equity-Linked Life Insurance**) in the put will also increase. The effect on the overall credit adjusted price of this defaultable option is not clear and in no way additive. Only an integrated analysis of the effect will reveal the proper price. Since this is more a valuation problem rather than a risk measurement topic, it is not elaborated further, but the reader may refer to e.g., [1, 2, 16].

Intensity Modeling: The Cox Process

A Cox process can be thought of as a Poisson process with a random intensity where the intensity is exogenous to the jump process, i.e., the occurrence of jumps is affected by the level of the intensity but the occurrence of jumps does not affect the intensity. This is in contrast, for example, with the self-exciting point processes, or Hawkes process, in which the occurrence of jumps leads to increased intensity. Here we focus on the one-dimensional case in which the process can be thought of as a simple counting process, but applications of the same construction are useful for more general point processes, for example, in modeling spatial patterns (*see Managing Infrastructure Reliability, Safety, and Security; Global Warming; Vulnerability Analysis for Environmental Hazards; Digital Governance, Hotspot Detection, and Homeland Security*).

Construction and Examples

The mathematical construction of a Cox process is most easily understood as a random time change of a standard Poisson process. Let λ denote a nonnegative stochastic process and define the nondecreasing process Λ as $\Lambda_t = \int_0^t \lambda(s) ds$. Assume that N is a Poisson process with intensity 1 that is independent of λ . Now define

$$Y(t) = N(\Lambda(t)) \quad (1)$$

We then say that Y is a Cox process with intensity process λ . We could have started directly with a nondecreasing process Λ and not insisted that it should be pathwise absolutely continuous with respect to Lebesgue measure, but here we focus on the intensity-based formulation, which is by far the most important for applications.

Some important special cases of Cox processes are as follows:

1. A Poisson processes with a deterministic, time-varying intensity. This corresponds to the special case where λ is a deterministic function of time. In queuing theory, (*see Large Insurance Losses*

Distributions) for example, the arrival rate of customers to a service stations often follow time patterns that can be described deterministically.

2. A mixed Poisson process. This corresponds to the case where each path of λ is constant but where the constant level is random. Here we can think of λ as a random variable. This is typically applied as a way of modeling arrivals of events in populations with heterogeneity.
3. A Markov-modulated Poisson process. In this case, the intensity process λ is controlled by a continuous-time Markov chain X , which for analytical tractability is typically assumed to have a finite state space. With a slight abuse of notation we write the intensity as a function of the level of the Markov chain as $\lambda_t = \lambda(X_t)$ so that $\Lambda(t) = \int_0^t \lambda(X(s)) ds$. This modeling framework has applications in a variety of fields. In queuing theory, the intensity of service may fluctuate owing to random breakdowns in components, in credit risk modeling the intensity of defaults may fluctuate owing to changes in business cycles, etc.
4. Intensity modulated by a diffusion or jump diffusion. This is similar to the Markov-modulated case except that the intensity is now modeled as a diffusion process or a diffusion with jumps.

Moments and Overdispersion

The assumption of independence between the intensity and the underlying Poisson process facilitates computation greatly since, after conditioning in the intensity, we can use properties of the Poisson process. For example, the mean and variance of Y are easily computed through conditioning:

$$\begin{aligned} EY(t) &= E(N(\Lambda(t))) = E(E(N(\Lambda(t))|\Lambda(t))) \\ &= E\Lambda(t) \end{aligned} \quad (2)$$

$$\begin{aligned} VY(t) &= E(V(N(\Lambda(t))|\Lambda(t))) \\ &\quad + V(E(N(\Lambda(t))|\Lambda(t))) \\ &= E\Lambda(t) + V\Lambda(t) \end{aligned} \quad (3)$$

where we have used the fact that the mean and variance of the unit rate Poisson process $N(t)$ are both equal to t . We note that the ratio of the variance

to the mean for the Cox process is greater than 1, which is the ratio of a Poisson process, regardless of its intensity. Consequently, the Cox process is said to display overdispersion relative to the Poisson process. This overdispersion merely reflects the fact that, in periods with low intensity, there are relatively few occurrences, whereas when the intensity is high there are many occurrences. Consistent with this observation, we note that the degree of overdispersion increases when the variability of λ , and hence of Λ , increases. Similar calculations show that the covariance between the number of occurrences in disjoint intervals is positive and the correlation increases with the variability in λ . In general, the moments of the Cox process are characterized by the moment properties of the directing random measure specified by the directing intensity. For more on this, see for example Daley and Vere-Jones [1].

Inference and State Estimation

The theory of inference and state estimation for point processes (*see* **Extreme Value Theory in Finance; Reliability Growth Testing**) developed strongly in the early 1970s. Typical problems involve the estimation of the directing intensity from observation of the jumps, for example, with the purpose of detecting change points. The dynamics of the underlying intensity may be known or may be parametric and parameters estimated as part of the exercise. The literature is very large and we refer to books by Snyder [2], and for the martingale methods refer to Brémaud [3], which contains an introduction and a comprehensive list of references.

A nice example of state estimation from observed occurrences in which solutions can be worked out explicitly is the case with a Markov-modulated intensity as studied in Rudemo [4].

An interesting aside is that one cannot always tell from the observed jumps of a point process whether the underlying structure is actually a Cox process structure. An example of this is attributed to Kendall (for a textbook treatment, see Resnick [5]), who showed that the linear birth process in which the intensity of new births increases linearly with the number of individuals in the population (i.e., a case where the intensity is not independent of the occurrence of jumps) can in fact be represented by a mixed inhomogeneous Poisson process where

the mixing variable is exponentially distributed and mixes between deterministic, exponentially increasing intensities. Other examples exist in which heterogeneity and contagion cannot be separated merely from observation of the Poisson process. A survey of some of the early contributions in this area can be found in Taibleson [6].

Example: Credit Risk Modeling

In this section we present a brief outline of an application (*see* **Credit Migration Matrices; Default Risk; Mathematical Models of Credit Risk; Copulas and Other Measures of Dependency**) of Cox processes in the area of financial economics and risk management. The largest source of risk for a typical commercial bank is the risk that borrowers default on loans granted by the bank. For a bank involved in trading of financial derivatives (*see* **Enterprise Risk Management (ERM); Actuary; Numerical Schemes for Stochastic Differential Equation Models; Default Correlation**), a similar important source of risk is the risk of default of a counterparty to a derivative contract with positive value to the bank. Quantifying such risks is a typical example of what is studied under the area broadly referred to as *credit risk modeling*. The fundamental problem in credit risk modeling is to model the price of corporate bonds, i.e., bonds issued by corporations. A corporate bond typically promises to pay coupons and repay principal in a manner similar to a government bond, but (in countries where we can think of a government bond as safe) the value of the bond is lower than that of the government bond. How much lower it is depends mainly on two quantities: the default probability of the firms and the recovery in the event of default, i.e., the fraction of the promised payment that is received in the event of default. In this presentation, we ignore the modeling of recovery and for simplicity treat it as zero, i.e., in the event of default on a corporate bond, the holder of the bond receives nothing. We focus now on why Cox processes are a convenient tool for modeling defaultable corporate bonds, emphasizing the point that the Cox process formulation allows us to apply tools developed for modeling the pricing and dynamic evolution of government bonds.

A fundamental relationship in the modeling of government bonds is the relationship between the

short rate of interest and the prices of zero-coupon bonds (see **Equity-Linked Life Insurance; Credit Migration Matrices; Mathematical Models of Credit Risk**). Zero-coupon bonds are bonds that pay no coupons before maturity but repay the principal at maturity. They constitute a basic building block for modeling all types of government bonds. The short rate is associated with a traded financial instrument, referred to as the *money market account*, which transforms a unit of account invested at time t into $\exp(\int_t^u r_s ds)$ units of account at time u . A fundamental result in financial economics states that for an economy with zero-coupon bonds trading (having maturities less than some terminal date T) under certain conditions there exists a probability measure Q such that for all pairs of dates $t, u < T$, the price at date t of a zero-coupon bond maturing at date u is given by

$$p(t, u) = E_t^Q \exp \left(- \int_t^u r(s) ds \right) \quad (4)$$

where E^Q denotes expectation taken under the measure Q and the subscript refers to information available at time t , which could be the sigma field generated by the factors driving the short rate up to time t .

Now turning to corporate zero-coupon bonds with zero recovery, we let the default time τ of the corporate bond issuer be modeled as the first jump of a Cox process with intensity process λ , i.e., τ is modeled as

$$\tau = \inf \left\{ t : \int_0^t \lambda(s) ds \geq E_1 \right\} \quad (5)$$

where E_1 is an exponential random variable with mean 1 (under the measure Q). To see how Cox processes bridge the link from corporate bonds to government bonds, consider the price $v(0, t)$ of a zero-coupon bond maturing at t with zero recovery in default and issued by a company with default intensity λ under the risk-neutral measure Q :

$$\begin{aligned} v(0, t) &= E^Q \left[\exp \left(- \int_0^t r(s) ds \right) 1_{\{\tau > t\}} \right] \\ &= E^Q \left[\exp \left(- \int_0^t (r + \lambda)(s) ds \right) \right] \end{aligned} \quad (6)$$

The functional expression for the defaultable bond now has the same form as that of a government bond but with an “adjusted” short rate $r + \lambda$ replacing the short rate r . This in turn means that explicit pricing formulas that exist for government bonds can easily be extended to corporate bonds; see for example Lando [7]. The explicit formulas can be obtained when r and λ belong to the class of so-called affine models, which are jump-diffusion processes in which the drift term, the squared diffusion term, and the jump intensity are all affine in the state variables. For a precise statement explaining this and elaborating on the computational advantages, see Duffie *et al.* [8]. Note that all these computational results pertain to computation of survival probabilities of the form $E \exp(-\int_0^t \lambda(s) ds)$ as well and therefore greatly improve our ability to perform calculations in diffusion and jump-diffusion (see **Lévy Processes in Asset Pricing; Default Risk**) driven Cox process models.

Cox-type regression models may be used to estimate the dependence of default intensities on covariates including company-specific key ratios (such as the amount of debt issued compared to the value of assets) and macroeconomic indicators (such as growth in gross domestic product (GDP)). The techniques are similar to those of survival analysis in biostatistics. However, for the models to be useful for pricing and for dynamic risk management, a full modeling of the stochastic behavior of the covariates is necessary as well. The Cox process structure facilitates the analysis by splitting the likelihood function for default events into a component describing the evolution of the covariates and a component describing the occurrence of jumps conditional on the covariates.

An important use of the Cox setting for modeling defaultable securities proceeds by treating the intensity process as an unobserved latent variable, which drives the price of a corporate bond, or a credit default swap, which is a contract insuring against the default of a particular bond issuer. In this case, the estimation of the underlying intensity process proceeds as a filtering exercise using the frequently observed price data as measurements. The driving intensity is then estimated using the Kalman filter (see **Nonlife Loss Reserving**); see Duffee [9] or using Markov chain Monte Carlo (MCMC) methods (see **Reliability Demonstration; Bayesian Statistics in Quantitative Risk Assessment**). This mainly works for corporate bonds with a fairly liquid market. For

valuing less liquid bonds or loans for which no market exists, one often has to rely on option-theoretic models or try to map the characteristics (such as industry and accounting ratios) of the issuer onto issuers of more liquidly traded bonds.

Recently, the market for credit derivatives has seen a rapid growth in so-called collateralized debt obligations (CDOs), which introduce products whose prices depend strongly on the correlation between default events of different issuers. A Cox process approach to modeling prices of CDOs can be found in Duffie and Gârleanu [10], where the default intensities of individual issuers depend on a “factor” stochastic intensity process affecting all issuers and idiosyncratic intensities that are specific to each issuer and conditionally independent given the factor intensity.

DAVID LANDO

Intent-to-Treat Principle

In a randomized clinical trial (RCT) (*see* **Randomized Controlled Trials**), subjects or patients are randomized to one or more study treatment or intervention arms. Ideally, randomization should occur after the investigators have verified that the patients have the disease under study and that they have met the eligibility criteria for entry into the trial. All patients who are randomized into a clinical trial comprise what is commonly referred to as the “intent-to-treat” population. In other words, all patients who are randomized are included in the analysis of the study results in the group to which they were assigned regardless of whether or not they received the assigned treatment [1–4]. The implications of this are several:

- If the patient is found not to have the disease under study, the patient remains in the analysis of results. This can occur, for example, when final verification of disease status is based on the results of special tests that are completed after randomization or on a central review of patient eligibility.
- If the patient never receives a single dose of the study drug, the patient remains in the analysis of results.
- If the patient does not comply with the treatment regimen or does not complete the course of treatment, the patient remains in the analysis of results.
- If the patient withdraws from the study for any reason, the patient remains in the analysis of results.

The intent-to-treat analysis based on the randomized treatment assignments allows us to conduct an unbiased test of the null hypothesis of no treatment difference (although an estimate of treatment effect may still be biased) and to attribute an observed difference to the treatment with a causal link [5]. The major issue for analysis, however, is how to handle those patients who did not receive the randomized treatment as planned owing to lack of compliance, side effects of the treatment, or other, possibly treatment related, reasons (*see* **Compliance with Treatment Allocation**). The proposed alternatives to intent-to-treat analysis include as-treated and

per-protocol analyses [1, 3]. Such analyses will result in distortions of the type I error rate as well as potentially biased estimates of the treatment effect [4, 6].

The interpretation of the results of any trial depends on the conduct of the trial as well as the analysis. The risks of reaching incorrect conclusions regarding the efficacy of a new treatment are increased with increased deviations from the planned design and randomization. For example, if there are differences in the eligibility rates, compliance, losses to follow-up, or withdrawal rates, which may be related to the treatment received, the overall estimated difference between the two arms may differ from the actual difference in efficacy. By using the intent-to-treat analysis, we estimate the effectiveness of the planned treatment strategies rather than efficacy directly. For example, if 90% of patients who are randomized to the new treatment refuse to take the treatment, even if the 10% of patients who do take the treatment have a 100% success rate (efficacy), the actual observed rate for the intent-to-treat analysis is 10%, which may be lower than the standard treatment rate.

In the case of a superiority trial, that is, an RCT designed to demonstrate that one treatment is superior to one or more other treatments, the intent-to-treat analysis is generally conservative. All patients who do not satisfy the conditions of the study at randomization or during the study are effectively treatment failures. If such patients are distributed equally among the several treatment arms, then any differences among the arms are generally reduced, and the effective study sample size is reduced. In such cases, if the results of the trial still indicate superiority, then while the estimate of effectiveness may be reduced, the overall conclusion would hold. If, however, any of these effects are differential between the treatment groups, the differences may be inflated in the intent-to-treat analysis [7].

In the case of noninferiority and equivalence trials (*see* **Inferiority and Superiority Trials**), the intent-to-treat analysis can bias the results in the direction of noninferiority or equivalence since the reduction in effective sample size produced by the inclusion of patients who were ineligible, noncompliant, etc., decreases the difference between the treatment groups.

When the intent-to-treat and the per-protocol or as-treated populations do not differ in any major ways, then the risks of incorrectly attributing efficacy (or

lack of efficacy) to a new treatment are reduced. Thus, it is critical that investigators design a study so that the eligibility criteria are clear, the treatment plan is well defined, and compliance issues are addressed.

Alternative approaches to statistical analysis have been proposed. These include longitudinal methods to handle dropouts [8], Bayesian methods to incorporate additional treatment information (such as rescue medications for treatment failures) using data augmentation algorithms [9], selection models that allow formal consideration of potential outcomes and pattern mixture models that model associations between observed exposures and outcomes [10], and the use of causal effect models for realistic treatment rules when the expected treatment assignment (ETA) is violated [11]. Hybrid intent-to-treat/per-protocol analyses that exclude noncompliant patients and incorporate the impact of missing data have been proposed for non-inferiority studies [12].

Supportive analyses always include analyses of patients who met the eligibility criteria; patients who met the eligibility criteria and received at least one dose of study medication; patients who met the eligibility criteria and completed the course of treatment (known as *per-protocol* population); among others. If all of the secondary and supportive analyses yield results that suggest the same conclusions as the results of the intent-to-treat analyses, then the trial is consistent. On the other hand, if the results are inconsistent in the various secondary and supportive analyses for the same endpoint, then it is the responsibility of the investigator to identify the reasons for the apparent differences, and the conduct of the trial may be an issue.

We note that any analyses of safety should be conducted on an as-treated basis.

Summary

In general, the intent-to-treat approach to the statistical analysis of RCTs is preferred to alternatives. However, investigators must provide a careful accounting of all patients randomized, all patients treated, and all postrandomization exclusions for lack of efficacy, lack of compliance, or lack of safety [4, 13, 14]. The intent-to-treat model provides a paradigm for the conduct of randomized trials that focuses on reducing any biases in patient assignment or evaluation of

outcome. However, the realities of clinical trial conduct can sometimes necessitate consideration of the deviations from the ideal model in the analysis.

Interpretations of Probability

Explicit and Tacit Probabilities

Except for a few scholars interested in mathematical esoterica, the familiar rules of probability, axiomized by Kolmogorov [1], are well established and generally agreed upon by researchers and practitioners. Despite this nearly universal agreement on its laws, people differ on the source and meaning of probability. Three dominant schools of thought are frequency probability, subjective probability (*see Subjective Probability*), and logical probability. All three traditions have a long history in mathematics and philosophy, and many pages have been written in support of and in refutation of these schools. What makes these continuing debates remarkable is that the quantification of uncertainty has been a tremendous achievement and benefit to society [2]. It appears in many diverse areas and forms the basis of empirical science, of legal evidence (*see Epidemiology as Legal Evidence*), of industries such as insurance and financial investments, and of artificial intelligence, to name just a few. Yet, we are none the closer to a consensus opinion about the meaning of “probability”. These differing interpretations of probability are more than moot academic arguments and can affect how insurance and risk professional approach problems. We often do not realize that we are taking sides in the debate because the interpretations are encoded in statistical software and standard methods.

Many practitioners, authors, and teachers, who are very adept with probability calculus, find it difficult to give a succinct interpretation without recourse to informal references to chance and uncertainty. Community standards may play a more important role in the interpretation of probability than, perhaps, mathematicians would care to admit. We develop our probabilistic intuitions through reference to various enumeration exercises and chance mechanisms. These insights do not come naturally, but require repetition and guidance by experts. The unnaturalness of probability and the need to transmit its meaning through formal education and socialization may be one reason that its development as a quantitative discipline traces only to the seventeenth century correspondence between Fermat and Pascal, while

gambling devices are found in prehistoric settlements, and qualitative expressions of chance and uncertainty appear in the earliest myths [3–5]. Using Polanyi’s [6] taxonomy of knowledge, the laws of probability are explicit knowledge: they are written down, accessible to everyone, and exist independently of the observer, while the interpretations of probability have a stronger resemblance to tacit knowledge, which is developed with experience, resides within individuals, and is transmitted through socialization. This tacit property may be the reason for several interpretations.

Relative Frequency

Most students start their probability and statistics training with probability being the same as relative frequency or proportion. A typical introduction will have illustrations similar to the following: “According to the Centers for Disease Control (CDC) (<http://www.cdc.gov>), there were 38 553 new diagnoses of HIV/AIDS in 2004 in 35 areas of United States with confidential name-based reporting, of which 10 510 were female. Consequently, the probability that a new diagnosis is female is 27%.” This approach provides a useful pedagogical device for illustrating the laws of probability to a general audience: all of the laws can be demonstrated with various cross tabulations. Not only are new HIV/AIDS diagnoses men and women, but they also can be classified by means of transmission. Then one could derive the probability of transmission through heterosexual contact to be 78% for women and 16% for men, and so on.

Relative frequency is an easy device to motivate the calculus of probability, but should proportions be evaluated to the stature of probability? To do so, teachers and authors add the tag line, “randomly selected”, as in “The probability that a randomly selected new HIV/AIDS diagnosis is a woman is 27%.” Sometimes, a student will ask, “Either the selected person is a man or women; what does 27% mean?” Teachers frequently invoke repeated sampling: if the sampling was repeated a large number of times (with replacement of course), then 27% of all resulting samples of size one will consist of a woman. Almost always, “randomly selected” is left to students’ imagination. Later, students learn that random number generators can be used for random selection. When asked

about the origins of random numbers, they are informed that computer programmers have conveniently worked them out. On deeper investigation, they discover that these sequences of numbers are deterministic and can be perfectly predicted if one knows the algorithm and its initialization: the correct phase diagram morphs these chaotic digits into patterns [7].

This vignette demonstrates the problem of revealing the meaning of probability. Relative proportions – 27% of new HIV/AIDS diagnoses are women – become probabilities – 27% chance of randomly selecting a woman – through a randomization mechanism. The randomization mechanism is not at all random, so probability becomes operationally defined by means of a deterministic process. Of course, one could roll a “38 553 sided die” or use some other randomization device, but then one needs to explain the meaning of probability for the “38 553 sided die”.

Not all is lost. One attempt to salvage the situation is the argument that “random selection” is an idealization that can only be approximated in reality. Calculations based on pseudorandom digits conform, to a high degree, to those derived from a random sample from a uniform distribution. The relative frequency that elements of a long series of digits belong to a subinterval converges in probability to the length of the subinterval; the average and variance of the digits will be close to $\frac{1}{2}$ and $\frac{1}{12}$; the autocorrelations of nonzero lag will be nearly zero; and so on. However, properties of the two do not perfectly match: the pseudorandom numbers will eventually repeat.

Every so often, a student will make the embarrassing observation that the original “27% probability of randomly selecting a woman” was an attempt to define probability, and the teacher merely transferred the definition of probability to an even more remote source – an idealized randomization device. The pseudorandom number generator is then certified by recourse to empirical evidence based on ill-defined inferential procedures that are inherently probabilistic: round and round the roulette wheel of circular interpretation spins.

A different attack is to use symmetry, the lynchpin of classical probability [8]. Though it is true that the random numbers are not actually random, there is nothing in their use that distinguishes one HIV/AIDS case over the other. Therefore, the random selection

process is indifferent to the case actually selected, and all outcomes are equally likely. Thus, the probability of randomly selecting a women patient *must* be evaluated at 27%. Symmetry arguments also apply to other phenomenon. Without further information about the physical process that flips a coin or rolls a die, a sensible observer would view all outcomes as being equally likely; hence one-half for a head and one-sixth for each side of a die.

The “must” injunction of symmetry arguments turns out to be more nuanced than it first appears. “Probability of randomly selecting a woman is 27%” may be a fair assessment if the person is selected with pseudorandom numbers. What if the randomization mechanism selects patients relative to their height? Then symmetry arguments would imply that the probability of a new HIV/AIDS diagnosis being a woman is less than 27% because the male distribution for height stochastically dominates the female distribution.

Subjective Probability

In using symmetry, our assignment of probabilities change depending on the assumptions we make about the population, sampling mechanism, or experiment. In other words, our probability assessments depend on our state of knowledge about the phenomenon. This marks a subtle and important shift in the interpretation of probability: the subjective one (*see Subjective Probability*). In the frequency interpretation, probability is an innate characteristic. Flipped coins come up heads 50% of the time because that is the property of coins. In subjective probability, flipped coins come up heads 50% of the time because the observer does not have information that would lead him or her to believe that one side is preferred over the other. The locus of uncertainty is not the coin and its environment, but resides within the observer. If the observer knew more about the physical laws of coin flips and the initial conditions, then he or she could refine his or her probability assessment.

The subjective interpretation provides advantages and challenges. By reporting internal states of uncertainty with probability, it frees practitioners to consider phenomenon that do not fit the repeated sampling framework. Underwriting insurance policies for large risk groups is well informed by relative frequencies, while they are less useful in certifying the safety of a new aircraft design. The relative

frequency approach would use accident rates of previous aircraft designs as the probability for the new design. A subjectivist could combine this historical data with engineering knowledge about the design and test results to arrive at an assessment of the design's safety. Even in setting a premium for an individual's life insurance, obtaining more information, including genetic data, about a policyholder makes it harder to identify the relevant reference population on which to base the life table. Structural breaks, such as the introduction of HIV/AIDS to the United States in 1981 and the subsequent treatment regimens and behavioral modification, can invalidate historical relative frequencies. In contrast, a subjectivist can freely combine historical rates with other information to arrive at an updated probability evaluation.

In addition to the flexibility of subjective probability, it neatly separates the interpretation of probability from inference while at the same time providing a unified method for inference and prediction through Bayes' theorem (*see* **Bayes' Theorem and Updating of Belief**). The frequentist reports the probability of obtaining a heads as $1/2$ if 50% of the tosses in a long series resulted in heads. This definition entwines the definition of probability with inference for that probability. A subjectivist reports the probability of heads as a distribution for possible values to reflect his or her knowledge, or lack thereof, about the phenomenon. If the subjectivist reports the probability θ of a head as a constant, such as $1/2$, then he or she is being very dogmatic in his or her beliefs and does not allow the possibility to learn from experimentation. If the subjectivist were uncertain about the exact value of θ , then he or she would give a prior distribution for θ . As outcomes of the flips are observed, Bayes' theorem is used to update the distribution for θ . The subjectivists incorporate relative frequency information from observations into a formal learning process that revises his or her beliefs about the probability of obtaining a head.

Making a Science out of Personal Beliefs

Challenges for subjectivists are twofold. First, why use probability for expressing beliefs? There is a large gap between the qualitative expressions, such as, "It is fairly likely that the new aircraft design is safe," to quantification: "The probability that the new design

will have an accident due to design flaws is 0.001%." An even larger gap exists between a quantification of one event to mandating that subjective beliefs for any and all collections of events *must* conform to the laws of probability. Second, how should one make a science out of a concept that is dependent on an observers' internal state?

Decision Theory

von Neumann and Morgenstern's [9] economic theory of rational choice provides a mechanism to show that a person's knowledge about uncertain events should be stated as probabilities by deriving them from the person's preferences. For example, the firm that designs a new airplane could choose either to manufacture and sell the new airplane or to cancel the program. If the firm sells an unsafe airplane, then it will incur a large financial and reputation loss, not to mention the human suffering it could cause. If it cancels a safe design, then the firm has an opportunity costs. Embedded within the decision lurks the firm's assessment of the safety of the design and the attractiveness of various gains and losses.

The primary object of the theory of choice is the preferences for actions available to the decision maker. If these actions (build the new design or cancel the project) satisfy a number of axioms, called the *axioms of rationality*, then a mathematician can derive a utility function on the space of consequences (financial gains and losses, opportunity costs, death, pain, and suffering) and a probability function on the space of events (safe or unsafe design) such that the ordering of actions based on preferences is the same as the ordering of actions based on expected utility (*see* **Subjective Expected Utility; Utility Function**). A mathematician can transform purely qualitative information about choices to numerical assessments of both utility and probability. The theory does not assume that people have probability distributions and utility functions and choose according to expected utility, but if their choices conform to the axioms or rationality, then their behavior is consistent with expected utility theory for some utility function and probability distribution. The converse is also true: if one orders actions according to expected utility, how every one arrives at utility and probability, one is guaranteed to be "rational". Thus, expected utility is the basis of decision theory (*see* **Decision Analysis; Decision Modeling**), and a person's belief

about uncertain events should be stated as probabilities.

von Neumann and Morgenstern assumed that there exists an unspecified, randomization device by which the mathematician is able to calibrate the subject's subjective probability for events. Their system is not useful as a definition of probability because it requires (frequency?) probability to define subjective probability. Savage [10] extended von Neumann and Morgenstern's axioms so that subjective probability can be derived internally to the subject's preferences, without reference to an external randomization device. The von Neumann–Morgenstern–Savage (NMS) model for rational choice not only requires that opinions about events conform to the laws of probability, but also provides an operational method to elicit those probabilities, along with utility functions, from observed preferences.

The NMS model depends on the context of the decision problem. Returning to the new HIV/AIDS cases, it may not be meaningful to ask for the probability of selecting a woman because the problem is devoid of a decision context: there are neither actions nor consequences. One way to provide a context is to give subjects a gamble, such as, "Suppose you will win \$1 if a randomly selected new HIV/AIDS case is a woman. What is the most that you be willing to play the game?" The modal answer is often well below 27 cents, which partly reflects risk aversion (see **Risk Attitude**), but more than likely for such small sums, merely reflects that the scenario is not designed to elicit the true or fair amount for playing the game.

Gambles and Coherence

Ramsey [11] and de Finetti [12] devised gambling situations that are less elaborate than the NMS axioms of rationality though special cases of rationality. To elicit honest responses, the subject is put into the scenario of a bookmaker (bookie) that states odds on events and must accept any sequence of bets, both positive or negative. The game goes as follows. The bookie (our subject) posts odds $P(A)$, $P(B)$, ... on the events $A, B, \dots$. A gambler, the bookie's customer, puts a stake S_A , which can be negative, on event A . It costs the gambler $S_A P(A)$ to play the game. If A occurs, the bookie pays the customer S_A , and the customer's total winnings are $S_A[1 - P(A)]$.

If A does not occur, the bookie pays the customer nothing, and the customer's total winnings are $-S_A P(A)$. Because the stakes on any event can be positive or negative, the bookie must judiciously select P to avoid becoming a sure loser regardless of the outcome. Being a sure loser is sometimes called *Dutch book*, and modern finance calls it *arbitrage*, which plays a central role in financial theory. de Finetti termed the specification of P that does not lead to arbitrage or Dutch book as being "coherent" or "coherently" stating one's beliefs. He shows that P is coherent if and only if it follows the laws of probability.

de Finetti's coherence theorem is very compelling for a bookie stating odds or a market maker quoting buy and sell prices. But not everyone faced with uncertainty wants to enter a casino, in which case they are free to quantify their beliefs however they choose. However, those of us who do not always conform to the strict dictates of rationality or coherence should be aware of the consequences of our departures, which, perhaps, points toward the role of education and socialization in understanding probability.

Social Determinates of Science

The second major obstacle for subjective probability is how to make a science from a concept that is focused on an individual's belief. An individual's belief about a gamble is a personal decision that only affects the gambler. What of an engineer's belief about the safety of a new aircraft design; an actuary's computation of premiums; or a medical researcher's belief about the efficacy of a new drug? The bookie and gambler paradigm may no longer apply because more is at stake than self-interest, and the consequence of these personal beliefs extend beyond the individual who holds them (see **Group Decision**). At the very least, will people examining the same data arrive at the same probability judgments? There is nothing in the theory of subjective probability that compels them to do so.

This nonuniqueness is a long-standing reason that frequentists reject subjective probability as a fruitful approach to science. The subjectivists' rejoinder is that objectivity is a chimera and that the best that one can do is to state underlying assumptions as accurately as possible and to present clearly the

evidence for or against a theory, so that other scientists can evaluate the results and update their probability assessments. Subjective probability fits better with science as a social endeavor where researchers marshal evidence to persuade colleagues about the suitability of a theory, which is then modified or discarded, than as a solitary pursuit of objectively knowable truth. Nevertheless, the frequentists' critique is true in an absolute sense: subjectivists believe in individual liberty to choose the probabilities that best fits their beliefs.

Inference and Prediction

These debates are far from inconsequential and affect how one approaches inference. Consider the model where $X_1, \dots, X_n$ is a random sample from a distribution with density f given an unknown parameter θ . The information in the data about θ is the likelihood function: $L(\theta) = \prod_{i=1}^n f(x_i|\theta)$. Members of both schools agree that the likelihood function summarizes the information in the data about θ . A subjective Bayesian adds his or her personal information about θ in the form of a prior distribution with density $p(\theta)$. The Bayesian then updates the prior opinions after observing the data $\underline{x}_0$ to obtain the posterior distribution with density $p(\theta|\underline{x}_0) = L(\theta)p(\theta)f(\underline{x}_0)$ where $f(\underline{x}_0) = \int L(\theta)p(\theta)d\theta$ (see **Bayesian Statistics in Quantitative Risk Assessment**).

Repeated Sampling versus Bayesian Learning

Frequentists make probability statements by integrating functionals of the data over possible values of X or the sample space, given the parameters. For example, for the parameter θ , Neyman's [13] 95% confidence interval has the form $LB(\underline{x})$ to $UB(\underline{x})$ based on the sample random sample $\underline{x} = (x_1, \dots, x_n)$. The bounds are constructed so that 95% of all possible samples of $\underline{x}$ will result in intervals such that the interval covers the population parameter: $P[LB(\underline{x}) < \theta < UB(\underline{x})|\theta] = 0.95$, which conditions on θ and treats the data as random. The inductive leap is that for the observed sample $\underline{x}_0$, we have 95% "confidence" that $LB(\underline{x}_0)$ to $UB(\underline{x}_0)$ contains θ . All Bayesian inferential statements are based on the posterior distribution $p(\theta|\underline{x}_0)$, which conditions on the sample information $\underline{x}_0$ and treats θ as random. A 95% highest posterior credible interval $LB(\underline{x}_0)$ to

$UB(\underline{x}_0)$ for θ is an interval such that given the data, the posterior probability that θ is in the interval is 95%: $P[LB(\underline{x}_0) < \theta < UB(\underline{x}_0)|\underline{x}_0] = 0.95$.

Neyman's repeated sampling framework created a paradigm shift in the scientific method and is still the dominant mode of inference. It provides an answer to the question of how sensitive the conclusions of a study are to random sampling. Inconsequential theories receive scant scrutiny, while success invites criticism; the subjectivists' critiques of the frequentists' inference is a case in point. Lindley [14] maintains that confidence intervals are a probability statement about the interval $LB(\underline{x})$ to $UB(\underline{x})$, given the parameter θ , while the proper focus ought to be the probability that θ is in the observed interval $LB(\underline{x}_0)$ to $UB(\underline{x}_0)$, given the data. Similarly, significance levels in hypothesis-testing report the probability of some aspect of the data, given the hypothesis, while science requires the probability of the hypothesis, given the data. This role reversal of random and fixed quantities in frequentist inference can lead to a number of anomalies owing to incoherency of not using a proper probability specification.

Exchangeability, Prediction, and Invariance

de Finetti's [12] exchangeability theorems provide a representation for subjective probability where the prior and likelihood function are jointly determined from a person's beliefs about observables. (See [15] for references that pre-date de Finetti.) Exchangeability means that the order of observations does not matter in probability assessments: $f(x_1, \dots, x_n) = f(x_{\pi_1}, \dots, x_{\pi_n})$ for any permutation $(\pi_1, \dots, \pi_n)$ in the order of the observations. All random samples are exchangeable, but not all exchangeable sequences are random samples. For infinitely exchangeable sequences the joint distribution of $X_1, \dots, X_n$ can be decomposed into a prior and likelihood: $f(x_1, \dots, x_n) = \int \prod_{i=1}^n f(x_i|\theta)p(\theta)d\theta$. One direction is trivial. If the observations are a random sample from $f(\bullet|\theta)$ given θ and if the prior for θ is $p(\theta)$, then the observations are exchangeable with marginal density $f(x_1, \dots, x_n)$. The other direction is of great importance. de Finetti argues that people have beliefs $f(x_1, \dots, x_n)$ about observables, not beliefs about

unobserved parameters. A mathematician can decompose an individual's specification for the joint distribution into a likelihood and a prior distribution, which is analogous to the theory of rational choice that deduces probability and utility from preferences.

Prediction becomes a simple task using the exchangeability representation. Given the data $X_1, \dots, X_n$, the predictive distribution for the next m observations, $X_{n+1}, \dots, X_{n+m}$ is:

$$\begin{aligned} f(x_{n+1}, \dots, x_{n+m} | x_1, \dots, x_n) \\ &= \frac{f(x_1, \dots, x_{n+m})}{f(x_1, \dots, x_n)} = \frac{\int \prod_{i=1}^{n+m} f(x_i | \theta) p(\theta) d\theta}{\int \prod_{i=1}^n f(x_i | \theta) p(\theta) d\theta} \\ &= \int \prod_{j=1}^m f(x_{n+j} | \theta) p(\theta | x_1, \dots, x_n) d\theta \quad (1) \end{aligned}$$

The predictive distribution depends on the data through the posterior distribution, which summarizes both the sample and prior information about θ . The prior, likelihood, and posterior are mathematically convenient devices to obtain the predictive distribution for future observations. In the HIV/AIDS example, the 10 510 female cases out of 38 553 new diagnoses are of interest only to the extent that they inform us about the predictive distribution of future cases, which de Finetti's bookies will use in posting betting odds.

Invariance representation theorems extend de Finetti's exchangeability representation theorems by identifying the form of the likelihood. For example, Freedman [16] and Kingman [17] show that spherical symmetry results in scale mixtures of independent normal distributions. The mixing distribution for the scale parameter could be viewed as a prior distribution, while the normal densities could be considered the likelihood function. Invariance theorems convert qualitative information about outcomes into formal, statistical models where "must" must hold. In subjective probability, the individual is free to assume or to reject invariance; however, if he or she accepts it, then the invariance theorems identify the appropriate families of distributions.

Logical Probability

The third interpretation of probability is logical or epistemic, proposed by Keynes [18] and elaborated by Carnap [19]. The logical probability of a hypothesis H given evidence E arises from the semantic relations among the statements that describe both hypothesis and evidence. In the sampling of women HIV/AIDS cases, we would assign a probability to the statement, $H =$ "There is a 27% probability of randomly selecting a woman", based on the strength of evidence contained in the statement: $E_1 =$ "10 510 women out of 39 553 new cases". Since we are not told about the sampling mechanism, we may assign a wishy-washy $P(H|E_1) = 0.5$, where $P(H|E_1)$ is the objective degree of logical support for H provided by E_1 . If we are informed about random selection *via* $E_2 =$ "Using a random number generator to select the case", then $P(H|E_1 \text{ and } E_2)$ is (nearly) one. On the other hand, if random selection is $E_3 =$ "Select the case proportion to the subject's height", and we know $E_4 =$ "The distribution of women heights are stochastically dominated by the distribution of men heights", then $P(H|E_1 \text{ and } E_3 \text{ and } E_4)$ drops to around zero.

Logical probability requires the specification of the joint probability of all relevant statements under consideration. Once one has this specification, it is possible to use the calculus of probability to deduce the degree of confirmation for any hypothesis based on any evidential statements. Specifying the joint distribution for logical probabilities is similar to specifying a rational preference structure for all possible actions in the theory of choice or the joint distribution for exchangeable sequences: all three are exceedingly difficult to do in practice.

Logical probability, as posit by Keynes, fell into disfavor, in part, because this joint probability for a collection of statements should be objectively evident to all who discern them, sometimes termed "necessary" probability. If one drops the "must" part of the probability assignments, most subjectivists do not have a problem with logical probability. In fact, Franklin [20] credibly argues that frequency and subjective probability are special instances of logical probability.

Logical probability has had negligible impact on empirical sciences; unlike frequentist or Bayesian inference, it has not developed a collection of models and methods for inference, hypothesis testing,

and forecasting. Nevertheless, the core ideas form the basis of artificial intelligence using Bayes nets, introduced by Pearl [21] (*see Expert Judgment; Influence Diagrams*). The nodes of a Bayes net are statements, and the arcs are probability assessments. Bayes nets express the semantic relations among statements, along with probability assessments. For instance, the nodes of a Bayes net for aircraft safety could include engineering specifications, flight conditions, and failure modalities. Bayes nets use the laws of probability to compute the probability of hypotheses, given the evidence. Many of us have unwittingly used Bayes nets; Microsoft Office's automatic help function is based on a Bayes net.

A Multifaceted Future

All human conflicts eventually come to an end, if not because there is a clear victor, then due to exhaustion. Academics in early and middle part of the twentieth century held strong beliefs about the interpretation of probability, and careers were made or lost depending on one's allegiances. Statisticians and researchers in the twenty-first century are more sanguine and flexible. Bayarri and Berger [22] note that the distinctions between the schools are less obvious, at least in practice. Researchers freely adopt the interpretation that best fits their needs, and few are interested in rehashing the battles of the twentieth century. Knowledge engineers who design Bayesian nets do not make a distinction between frequency, subjective, or logical probabilities: they use any variety that is available and reliable. Researchers and risk professionals readily flip between frequency and Bayesian methods. Hybrid Bayesian use subjective priors and frequentist likelihoods – likelihoods determined from the observed variation of the data and not based on prior beliefs. Computational Bayesian employ frequentist concepts when analyzing the output of Markov chain Monte Carlo simulations, and frequentist often treat p values as the probability of the null hypothesis and interpret confidence intervals as subjectivists. No longer are priors reflexively shunned in scientific journals; they are critiqued as one aspect of the research design. The advancement of science requires the intelligent and sensible construction of models, appropriate use of methodology and measurement, and trust that researchers accurately portray their findings. The dogmatic adherence to schools of interpretation

will not compensate for ill-conceived measurements, poorly designed and executed experiments, inadequate models, or unethical researchers. The interpretation of probability will continue to evolve over time, and education and social processes, enabled by user-friendly software, are bound to blur further the distinctions among the different interpretations of probability.

Acknowledgment

I wish to thank Bruce Hill for his insight and knowledge about subjective probability, and Simon French and Michel Wedel for commenting on earlier drafts.
